This number contains the following original memoirs relating to chemistry and collateral subjects:—

Experiments Made with the View to Determine the Course of the Bumerang.—W. Stille.

Mineralogical Communications.—G. vom Rath.—The eleventh portion of this monograph, this section treating on an orthite; illustrated by engravings.

Influence of the Stiffness, Mode of Fastening, and Amplitude on the Vibration of a Chord.—F. Braun.

Spectra Exhibited by Phosphuretted Hydrogen and Ammonia.—Dr. K. B. Hofmann.—Illustrated by engravings.

Evolution of Light by the Motion of Atoms.—F. Hoppe-Seyler.

Nitric Anhydride (Salpetersäures Anhydrit), and a New Hydrate of Nitric Acid.—R. Weber.—In the introduction to this paper the author refers at some length to the researches of Deville, Odet, and Vignon on the anhydrous nitric acid prepared by the action of chlorine upon dry nitrate of silver, and also to the earlier experiments of Thenard, Gay-Lussac, and others for dehydrating strong nitric acid by means of sulphuric acid. The author next describes at length a series of experiments which show that, after having prepared a concentrated nitric acid by re-distilling several times a mixture of strong nitric and concentrated sulphuric acids by the action of pure phosphoric anhydride (care being taken to keep the nitric acid cold by means of ice applied to the vessel wherein it is contained) nitric acid may be obtained in the solid anhydrous crystalline state. This substance has a sp. gr. of 1.64; it is rather prone to spontaneous decomposition, especially at a somewhat high temperature (above 10°); sulphur, phosphorus, and the readily oxidisable metals (potassium and sodium) act upon this anhydride energetically, but carbon, aluminium, zinc, cadmium, iron, nickel, titanium, copper, lead, tin, bismuth, antimony, tellurium, and thallium are quite passive with this substance; pure clean silver and palladium are not acted upon by it, but metallic arsenic and mercury are oxidised. Upon many of the organic substances this nitric anhydride acts strongly, and it combines with water in the same way as hydrosulphuric acid; it also combines with strong nitric acid, forming a peculiar hydrate, a crystalline substance, consisting of—Nitric acid, 92.31 per cent; water, 7.69. Formula, 2NO₃ + H₂O.

Behaviour of some Alkaloids Towards Sugar and Sulphuric Acid.—R. Schneider.—After briefly referring to Schultze's discovery that several protein compounds and also some fatty oils exhibit a peculiar purplish colour when mixed with sugar and sulphuric acid, the author states that he has found that several alkaloids—Morphia, codeine, narcotine, and narceine—behave in a somewhat similar manner when brought into contact with sugar and sulphuric acid; but the cinchona alkaloids and strychnia, brucia, atropine, colchicine, emetine, and picrotoxine do not exhibit such a reaction; atropine assumes a rose-red colour under the same conditions; delphinine turns at first yellow, but soon becomes brown, and, upon the addition of a single drop of water, of a beautiful green colour; chelidonium treated with sugar and sulphuric acid yields a colouration somewhat like that exhibited by strychnia when treated with sulphuric acid and bichromate of potassa.

Contributions to Micro-Mineralogy.—Dr. von Lasaulx.—The second part of a monograph on this subject.

Dynamical Theory of Gases.—V. Lang.

Les Mondes, October 10, 1872.

Theory of Fermentation.—Prof. Pasteur.—From the abstract here published it appears that the celebrated *savant* has recently found that saccharine liquids (must from grapes, malt infusions, &c.) do not enter into alcoholic fermentation solely by contact with oxygen, but that the introduction of germs or dust (*poussières*) present upon the fruit of the vine is absolutely required to cause fermentation; this fact is experimentally demonstrated by the description of the mode of operating. The author also briefly alludes to some recent researches made by him, from which he draws the conclusion that two different orders of living beings exist in Nature—one of which, visible to the naked eye, requires free oxygen for sustenance; while the other, microscopically small objects, is killed by free oxygen, but lives upon that drawn from any of its combinations, carbonic acid for instance. Fruit (apples, pears, peaches, &c.) continues to live after being pulled from the trees which produced it, and, while exposed to free circulation of air, absorbs oxygen, exhales carbonic acid, and ripens. When fruit is exposed to an atmosphere of carbonic acid, this kind of life ceases, and the fruit, being prevented from absorbing oxygen, begins to assimilate oxygen from its own juice (saccharine material), the result of which is that a veritable alcoholic fermentation is set up, whereby the fruit becomes soft, and yields, on being submitted to distillation, pure alcohol, while carbonic acid is given off. This communication is as yet a preliminary one, since the researches are not yet complete,

International Congress for Weights and Measures.—Rev. F. Moigno.—The author states that great progress has been made for the definitive adoption of the metric system as a universal international system, and that the members of the Congress agree on all really essential points.

Petites Annales de Chimie.—E. J. Maument.—The seventh portion of this monograph, elucidated by a series of algebraical and chemical formulæ, and intended to simplify the theory of chemistry according to certain views of the author.

Caravane Universelle.—Captain Bazerque.—Under this title the author publishes an exhaustive programme of an intended scientific exploration of the different parts of the world, aided by all the means that science, industry, and commerce can supply, for the purpose of furthering friendly intercourse between different nations and tribes, as well as for geographical, meteorological, and other scientific objects.

Universal Carcel Lamp with Double Air-Draught and Compensation.—Rev. F. Moigno.—The author briefly describes a new kind of oil-lamp, constructed upon very improved principles by A. Bernard and Co., Paris, which, when applied without reflector, gives a light equal to that of thirty standard candles, and, with reflector, a light equal to that of fifty. Having been tried as a signal-lamp on board a French man-of-war, it has been found, with a slight alteration in the burner, to yield a light distinctly visible at a distance of 10 French sea-miles = 55,555 metres = about 34½ English statute miles.

Bulletin de la Société Impériale des Naturalistes de Moscou, No. 1, 1872.

It rarely happens that this periodical, which is chiefly devoted to natural history, contains an original paper relating to chemistry; we find, however, in this number the following memoir:—

Researches on the Compounds of Ilmenium and Niobium, and on the Composition of the Niobium-Containing Minerals.—R. Hermann.—This is the first part of an exhaustive monograph on this subject, elucidated by a series of formulæ, and divided into the

following sections:—Preparation of $NbNb_2$ and of $IlIl_2$ from a mixture of columbite and ferro-ilmenite from Haddam; separation of the acids of niobium and ilmenium by fractional crystallisation of their potassium fluorides, and preparation of their soda salts; composition of the metallic acids contained in the Schuchardt's mineral powder; soda salts of the niobium acids; soda salts of the ilmenium acids; atomic weight of niobium; specific gravity of niobium and its atomic volume; brown niobium oxide; green niobium oxide; niobium oxide, (NbO) ; niobous acid, (Nb_2O_3) ; hyponiobic acid, (NbO_2) ; niobic acid, (NbO_3) ; niobium sulphuret, (Nb_2S_3) ; niobous chloride, (Nb_2Cl_3) ; niobous oxychloride, $(Nb_2O_3 + nCl_2)$; yellow niobium chloride, $(NbCl_5)$; niobium and fluorine; combinations of fluor-niobium and fluor-potassium; combinations of potassium-niobium-ilmenium fluoride; fluorides of niobium and sodium; combinations of fluor-niobium and ammonium fluoride; fluor-niobium and fluor-zinc; fluoride of copper and fluoride of niobium; compounds of the niobium acids with bases, viz., potassa, soda, ammonia, magnesia, oxide of iron, oxide of copper, protoxide of mercury, and oxide of silver.

Journal für Gasbeleuchtung und Wasserversorgung, Nos. 16 and 17 (double number), 1872.

Tessie du Motay's Gas-Lighting Method.—E. Mack.—From this brief report of the author's lecture we learn that important improvements have been made by B. Andree in the preparation of oxygen, and the gas-burners have been so altered as to admit of the oxygen flowing out towards the periphery of the coal-gas flame. It further appears that at Vienna, and in other parts of the Austro-Hungarian Empire, this method of gas-lighting is also generally approved of in consequence of its small expense.

There is published in this number the detailed description, illustrated by several engraved plates, of an experimental gas-work devised by the committee of the German Association of Gas-Managers appointed to report on this subject.

Polytechnisches Journal von Dr. E. M. Dingler, first number for September, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Application of the Papin Digestor for Culinary Purposes.—Professor Junichen.—This paper treats on the use which might be made of the so-called Papin digestor under high pressure, for the purpose of boiling meat and other food. From a tabulated form added to this paper, it appears that the author's experiments prove that the time for cooking various articles of daily consumption is very much shorter when effected under strong pressure, while a great saving in fuel is also obtained.

Analysis of Crystalline and Amorphous Bottle-Glass.—Dr. H. Schwarz.—The crystalline variety (obtained from Siemens's glass-works at Dresden) contained, in 100 parts—Silica, 58.65; alumina, 7.22; peroxide of iron, 2.03; protoxide of manganese, 5.68; lime, 15.18; magnesia, 0.31; soda, 9.97; potassa, 1.03. Formula— $16SiO_2 + 2Al_2O_3 + 13RO$.

Amorphous glass contained, in 100 parts—Silica, 59.33; alumina, 7.69; peroxide of iron, 1.89; protoxide of manganese, 6.30; lime, 14.73; magnesia, 0.35; soda, 9.70; potassa, 1.36. Formula— $17SiO_2 + 2Al_2O_3 + 13RO$.

The sp. gr. of the crystalline glass was found to be, at 15°, 2.660; that of the amorphous, 2.648.

Venetian Mosaic Glass.—Dr. H. Schwarz.—A sample of the bright blue-coloured Mosaic glass, from Salvajoli's celebrated works, was found to consist, in 100 parts, of—Silica, 64.70; alumina, 2.0; peroxide of iron, 0.54; oxide of antimony, 5.92 (the semi-opacity of this glass is due to this substance); oxide of lead, 9.76; oxide of copper, 1.34; lime, 3.04; potassa, 2.05; soda, 9.98.

Decolorising Action of Animal Charcoal.—Dr. H. Schwarz.—This essay records the results of a series of experiments made with the view of ascertaining whether, by igniting bone-ash with organic substances, such as glue, size, sugar, &c., a good decolorising charcoal is formed, and also whether the spent animal black can be revived to its former strength by a similar process. It appears from the author's extensive researches that animal black may be entirely revived in closed vessels by ignition with organic matter, which need not be nitrogenous.

Quantity of Manganese Contained in Various Kinds of Steel.—Dr. F. Keszler.—Krupp's cast-steel contains from 0.437 to 0.438 per cent of manganese; Bochum cast-steel, from 0.312 to 0.317; Hasper steel, 0.327 to 0.332; Hörder steel, 0.167 to 0.170; Krupp's cannon steel, from 0.185 to 0.207; Ludwig's (at Berlin) manganese steel, 0.303 of manganese and 0.31 of silicon; English pig-iron (Askam and Miliron, Cumberland), from 0.080 to 0.105 of manganese; piano-wire made from best Swedish iron, 0.035.

Studies for Establishing a Scientifically-Arranged Tanning Method.—A. Reimer.—The conclusion of this monograph; this portion is divided into the following sections:—On the part which the different portions of the skin play in the process of tanning (tawing) with alum and common salt; corine with alum and common salt; the fibres of the cellular tissue; general conclusions to be drawn from the researches; tanning experiments with iron alum and chrome alum; skin and iron salts; experiments with oak tannin (quercotannic acid), general conclusion; the behaviour of skin towards tanning materials, and that of animal fibres towards dyes. The behaviour of charcoal with dyes and tanning materials belongs to that class of phenomena which are designated as surface attraction (*Flächenanziehung*).

NOTES AND QUERIES.

Transparent Cement.—I should feel greatly obliged if you would kindly tell me the ingredients used to make a liquid transparent cement to stand hot water.—OMICKA.

Constituent Fatty Acids of Palm-Nut Oil.—(Reply to F. H. T. A.)—This correspondent will find the information he requires in Wagner's "Chemical Technology," recently published by Messrs. J. and A. Churchill.

Sugar-Refining.—Works on Organic Chemistry.—Would your readers kindly inform me where I can find the best information about the modern methods of sugar-refining; and what are the best works on organic chemistry, especially in regard to recent research, for a student who is well acquainted with Miller's third volume?—A. J. W.

Fusion-point of Cæsium.—(Reply to Dr. W. Hall.)—It appears that cæsium has not yet been obtained in free metallic state; an amalgam with mercury has been formed; the equivalent weight of cæsium (Cs) is 133.

TO CORRESPONDENTS.

T. Fletcher, C. T. Kingszett, L. Browne, R. Apjohn, G. Ainsworth, W. Baxter, Prof. Galloway, Prof. Henry Morton, E. Stenstedt, C. R. C. Tichborne.—Received with thanks.

Percolator.—We have often given processes for protection of wood from fire. Consult Index; also No. 569, Sept. 20th.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON AND HENRY WATTS. Second Edition, illustrated with numerous Wood Engraving.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gum-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIÈRE AND CO., 40, King William Street, Strand.

THE CHEMICAL NEWS.

Vol. XXVI. No. 674.

CHEMISTRY IN INDIA.

COMPLAINTS are often made (and it must be admitted that there is some reason for them) that, on the occurrence of vacancies, chemical appointments in England are not always given to the most distinguished chemists who apply for them. What, however, should we think if the chemical chair in a first-rate hospital in London were given, not to a chemist by profession, but to a medical man who was supposed to know a little chemistry? What would be said if our friend Mr. Roberts were to be replaced at the Mint by a general medical practitioner? and if the testing of the metropolitan gas were to be handed over to some member of the medical faculty supposed to have chemical proclivities?

Such things are done in our Indian Empire, where, in addition to the many calls upon the medical profession, there falls the burden of supplying professorships of chemistry in medical colleges, chemical examinerships, assay-masterships, inspectorships of gas-works, and the like. The medical profession, although a most learned profession, cannot satisfactorily discharge all these functions. We are informed, moreover, that in one notorious instance all the offices which we have just enumerated are undertaken, not by several members of the faculty, but by one solitary medical practitioner.

The state of things in India may be imagined by such of our readers as may happen to know what a medical school used to be in times gone by, when chemistry was taught from books that stated "a stream of sulphuretted hydrogen throws down a dark green precipitate from the solution of copper." Our readers will be inclined to add that, in this instance, the green is very dark, and that it is commonly called brown or black.

It is not beyond the bounds of possibility that such a book may be in the hands of some of those medical gentlemen who have undertaken to act as chemists in India. We are in possession of details respecting the manner in which chemical operations are conducted in India, which show that, whether or not the book from which we have quoted be received as a text-book, there is imminent need of reform.

It should be known that the Indian Government set up cinchona plantations at Ootacamund, in the Madras Presidency, and at Raungbee, in Sikhim, Bengal, for the laudable purpose of supplying the fever-stricken millions of India with cheap quinine. Someone found it to their interest to lead the Madras Government to suppose that an admixture of inferior alkaloids did not cause deterioration of the quinine, and that consequently it might be hoped to supply an "amorphous quinine" at one shilling the ounce. Such hopes were, of course, delusive, and the Government are furnished with a substitute for quinine, consisting of a mixture of unbleached alkaloids, containing 18 per cent of pure quinine, 54 per cent of cinchonidine, 13 per cent of cinchonine, the remainder being colouring matter, &c. This mixture, it appears,

is supplied at a cost which, according to various accounts, is from 60 to 80 per cent of that of the best quinine, and at a considerable loss on the real market value of the drug. The constitution of the Raungbee drug is reported to be even still worse, since the presence of quinine was quite cast in the shade by that of copper to the extent of at least *ten per cent.* But even for India this was too much, and the works have been placed under the care of a new superintendent, from whom we may hope to obtain at least a purely vegetable product.

The question may be asked, whether the chemical appointments are sufficiently well paid to induce talented chemists to seek them; and in reply it can be stated that, with a salary of £1000 to £1200 a year, and a healthy hill climate with a mean annual temperature of 54° F., India offers a fair field to every English chemist who is willing to go there.

ON THE MANUFACTURE OF PURE SULPHATE OF POTASSIUM.

By E. SONSTADT.

Most of the sulphate of potassium known in commerce consists essentially of the double salt $3K_2SO_4 + Na_2SO_4$. According to Dr. Penny's investigations, this salt, when its solution is repeatedly crystallised, affords crops of salts of variable composition, but in which "plate sulphate" and sulphate of sodium predominate. M. E. Peligot, on the other hand, in a paper, "Sur la Répartition de la Potasse et de la Soude dans les Végétaux,"* proposes, as an analytical method, the separation of the sulphate of potassium and sodium by crystallisation, and in respect to plate sulphate makes the following remark:—"J'ajouterais que les sulfates doubles des potasses et de soude ne se produisent que dans des conditions exceptionnelles tellement rares, que M. Des Cloizeaux a eu beaucoup de peine à s'en procurer quelques échantillons. C'est surtout lors de la cristallisation des sulfates, en présence d'une liqueur alcaline contenant du carbonate de potasse et du carbonate de soude, que ces sels ont été quelquefois obtenus. Ces conditions se trouvent réalisées dans les urines où l'on raffine les potasses provenant des salins de betteraves." M. Peligot's own results do not appear to have been subjected to the control of analysis, he contenting himself solely with reference to the crystalline form of the salts obtained, and to their character as to efflorescence in air.

About three years ago I was induced—by the difficulty I experienced in obtaining pure carbonate of potassium, free from sodium, in commerce, fit to be used in the manufacture of iodide of potassium—to experiment upon the manufacture of a pure sulphate of potassium from plate sulphate. These experiments cost me nearly a year's labour, and were conducted not only in the laboratory, upon small quantities, but also at works where a few hundredweights could be treated at a time. The statement made by Peligot, that plate sulphate can only be crystallised from an alkaline solution, is not correct. Plate sulphate crystallises from perfectly neutral solutions of sulphate of potassium, containing a certain proportion either of sulphate of sodium or of chloride of sodium. But a solution of pure plate sulphate (sodio-tripotassic sulphate), when slightly concentrated, so as to give only a very small crop of crystals on cooling, deposits pure sulphate of potassium. If the liquid is saturated when hot, and allowed to cool, the crop of crystals obtained consists chiefly of plate sulphate. By repeated crystallisations crops are obtained chiefly of potassium sulphate, containing less sodium sulphate than plate sulphate, with

* *Annales de Chimie*, December, 1867.

occasional crops of plate sulphate and of sodium sulphate towards the last. These results, therefore, agree substantially with those obtained by Dr. Penny. I tried also "salting out" continuously from a boiling solution of plate sulphate, and found that the sodium accumulated in the salts separated during heating, but only up to a certain point. I also alternated these modes of treatment in many ways, but still unsuccessfully, so far as concerned the effective separation of the sodium from the potassium sulphate. Having failed in these attempts, I studied the mutual influence upon one another of the chlorides and sulphates of sodium and of potassium in promoting or retarding one another's solubility, and the experiments soon led to the process of purification indicated by the equation—

In practice, 664 parts plate sulphate are added to as much boiling water as will dissolve the whole; 149 parts chloride of potassium are then added to the hot solution by small portions at a time. As the chloride of potassium dissolves, pure sulphate of potassium precipitates as a crystalline powder. The liquid is allowed to cool, when more pure sulphate of potassium crystallises out. The mother-liquid is then evaporated until it becomes saturated at boiling temperature, and, on cooling, deposits another crop of pure potassic sulphate; and this process may be repeated three or four times, until the liquid becomes saturated with chloride of sodium, after which any further crops obtained would be chiefly of plate sulphate. When the muriate used in this process contains, as it usually does, a few per cents of plate sulphate, this small proportion of plate sulphate does not dissolve, but becomes mixed with the first crop of pure sulphate, and as some mother-liquor adheres and dries up upon the sulphate, the latter, in practical working under ordinary conditions, may contain as much as 3 per cent of sodium sulphate, equal to nearly 1 per cent of sodium. When the chloride potassium used is pure, as in laboratory experiments, and the sulphate obtained as described is carefully washed free from the mother-liquors, it is pure. But in practice, when—as in the manufacture of iodide of potassium—a perfectly pure potassic sulphate is required, it is better to re-crystallise the sulphate first obtained, which is then chemically pure.

These experiments have been controlled throughout by carefully-executed analyses of the salts obtained. In the earlier analyses made in the course of the investigation the sulphuric acid and the potassium were separately estimated; but in the later analyses only the sulphuric acid was estimated, and the atomic weight of the base thence deduced, in the absence of chlorine. In the sulphate of potassium that I have described as pure the atomic weight of the potassium—calculated from the sulphate of barium obtained—was usually 39.13, and rarely fluctuated more than between 39.1 and 39.2. In these analyses certain precautions must be taken,—especially that the solution of the specimen of sulphate of potassium should be *dilute*, and that the chloride of barium should be added all at once in *slight* excess, and be quickly stirred up. With these precautions the sulphate of barium precipitated is quite pure, after proper washing with pure water.

ON A MEANS OF PREVENTING EXPLOSIONS IN COAL MINES.

By JOHN A. R. NEWLANDS, F.C.S.

DIMINISHED atmospheric pressure is frequently followed by the escape of fire-damp into the workings of a colliery. To obviate the risk incurred by such barometrical changes I propose that artificial means should be adopted, so as

to maintain the atmospheric pressure within a given mine always at one and the same level, and also, if desired, to work under a somewhat increased atmospheric pressure. Taking the case of a mine having a downcast and an up-cast shaft, the mouth of each of these should be covered over by an air-tight chamber, capable of withstanding a moderate pressure either from within or without. This air-tight chamber might be conveniently constructed of sheet-iron, provided with thick glass windows: it should also be made sufficiently large to admit of all the usual operations at the pit's mouth being conducted within it. The shaft of the engine used for raising coal would pass through the sides of this air-tight chamber, so as to move the necessary hoisting apparatus within. Connected with this air-tight chamber an air-tight room should be constructed, provided with two sliding doors, the inner door separating it from the air-tight chamber, and the outer door preventing contact with the external atmosphere. It will be seen at a glance that when the outer door of the room is shut, and the inner open, the room becomes part and parcel of the air-tight chamber, so that any truck laden with coal might be run from the air-tight chamber into the room, and then (by closing the inner door of the room and opening the outer) on to the ground surrounding the pit's mouth, without sensibly altering the pressure within the pit itself.

To produce the requisite current of air for ventilating the pit the air-tight chamber over the downcast shaft should be connected with powerful air-pumps, worked by steam, so that a continuous current of fresh air might be forced through all the workings of the pit before finally escaping through a pressure-valve from the air-tight chamber over the upcast shaft. Any required degree of ventilation, or of increased atmospheric pressure, could thus be produced within the pit. As no fire would be wanted in the upcast shaft, it would be available for hoisting coal, &c. The air supplied to the mine might, if required, be easily cooled, by compressing it in cylinders surrounded with cold water before allowing it to pass into the pit, and thus the temperature of the pit might be reduced to any extent. The air issuing from the pit should be chemically tested at stated hours, and whenever the fire-damp appeared to be increasing the men and horses should be brought up, and the air-pumps should be employed in drawing air out of the mine, so as to diminish the pressure within, and thus cause any imprisoned marsh-gas to be brought out of its hiding-place. After keeping the mine under diminished pressure for some hours, a rapid current of air should be driven through the workings, and when—by testing the air passing through the escape-valve—it was found to be nearly pure, operations could be safely recommenced.

CHEAP SALINE DISINFECTANTS.

By SIDNEY W. RICH.

A PAPER read by Mr. E. C. C. Stanford at the last meeting of the British Pharmaceutical Conference, has induced me to make the following remarks. The paper alluded to was entitled "A Cheap Disinfectant," and affected to demonstrate the superiority of chloride of calcium as a disinfectant over hydrochlorate of alumina and other saline disinfectants. Although I give no tabulated experimental results, I may state that the remarks I now make are based on the experience derived from a large amount of experimental labour devoted to a study of the relative power of these salts when applied to animal and vegetable solids and fluids, and also sewage.

The number of cheap saline disinfectants found efficacious under ordinary circumstances, may be counted on the fingers. The chlorides and sulphates of iron,

aluminium, calcium, and sodium, complete the list. A few words devoted to each of these may help to give a clear idea of their respective values.

The chloride and sulphate of sodium are simply preventive, or antiseptic, although in a less degree than the free acids. They have no disinfecting or absorptive power. The extensive use of chloride of sodium (common salt), is due partly to its cheapness and convenient form, and partly to the fact that it has always been an article of commerce and domestic use.

Sulphate of calcium (gypsum) has long been used as a disinfectant, more particularly on farms and in stables. Its absorptive action is very considerable, both in respect to ammoniacal products, and, in a mechanical way, of the other products of decomposition. Owing to its slight solubility, however, it has no great action as a preventive, and the same reason confines its use to the disinfection of solid matters. It cannot be used for fluids, or allowed to enter the drains.

The value of chloride of calcium as an antiseptic is about equal to that of common salt, but it possesses, beyond, the power of absorbing the ammoniacal products of decomposition, and to that extent a disinfecting power. It has, however, no power to absorb mechanically the other products of decomposition.

The sulphate of aluminium and hydrochlorate of alumina are powerful disinfectants and antiseptics to an extent beyond any of the bodies of which we have yet spoken. As antiseptics these salts are nearly, if not quite, as efficacious as the acids themselves, while free from the objections which attach to the use of the latter. Their absorptive action is exerted on the ammoniacal products of decomposition; and also by virtue of the mechanical action of the hydrated alumina, which is precipitated immediately these salts are brought in contact with decomposing matter, or the other products of the said decomposition. The solubility and harmlessness of these salts renders their use admissible under all ordinary circumstances; while the lightness of the precipitate of alumina secures immunity from any danger of choking the drains. The hydrochlorate of alumina appears to be somewhat more powerful than the sulphate of aluminium.

The chloride and sulphate of iron have all the action of the corresponding aluminium salts, and, beyond, they possess the power of absorbing the sulphuretted products of decomposition. This latter fact places these salts at the top of the list in respect to efficacy. There are, however, some objections to the use of these salts, the principal being that when used in large quantities for ordinary purposes, the iron itself is likely to be injurious to the vegetation with which the fluid or other matter may ultimately come in contact.

Apart from the question of price, the conclusion to be derived from the above observations is manifestly as follows. That the greatest efficacy and general applicability will be found in a solution containing hydrochlorate of alumina with a small quantity of chloride of iron. The hydrochlorate of alumina will serve to do the general work of a disinfectant and antiseptic, while the iron salt will absorb the sulphuretted compounds which arise from the decomposition of some kinds of organic matter.

The chloride of calcium is the cheapest, inasmuch as it is a waste product in all alkali works. In this particular, hydrochlorate of alumina will, however, be able to compare favourably in the future as the result of late improvements in the manufacture of alum will be to cause the manufacture of large quantities as a waste product.

In recommending chloride of calcium as a disinfectant, Mr. Stanford recommends that the solution should contain 25 per cent of the solid salt, acidified with 12 per cent of hydrochloric acid. Certainly, such a solution would have a considerable disinfecting power, but most chemists would attribute this to the hydrochloric acid. Moreover, a solution containing 12 per cent of hydrochloric acid would be a very disagreeable fluid for ordinary purposes.

THE EARTH SALTS OF BELLARY.

By EDWARD NICHOLSON,

Assistant Surgeon, R.A.; Analyst of Waters, Mysore, Northern and Ceded Districts.

THE soil of the Ceded Districts yields three saline products—salt, nitre, and soda. I have lately examined the first two of these in the course of my investigations on the peculiar salinity of wells sunk in black cotton soil.

Salt.

Any person who has been in Bellary must have remarked mounds of black cotton soil here and there about the outskirts of the cantonment. These mounds are raised for the purpose of being worked for earth salt; when exhausted they are abandoned, and become gradually levelled by the scanty rain of years. They are generally situated not far from the lines of drainage of the country at any convenient spot where the soil is saline, and water can be easily obtained. Patches of the most saline earth, tested in a simple manner by application to the tongue, are dug up and heaped in a mound 10 or 12 feet high; at different levels of the mound funnels are excavated and lined with beaten earth, and the loose earth being placed in these is gradually exhausted by repeated washings. The water having been sufficiently charged with salts in its passage through the different funnels, is run on to a level floor of rammed earth surrounded by a low rim. Under the influence of Bellary sun, evaporation is effected in a few days, and a residue of salt is left. This is piled in heaps for any moisture (bittern) to drain off, and when dry, it is sold to the villagers for domestic consumption. The wholesale price is about 30 seers (measure) for a rupee; it is retailed at about eight cash per seer (a penny per quart), which is half the price of sea-salt. It is not usually sold in cantonment, as it is never used by the population of sepoys, camp followers, and other people not belonging to this part of the country, its use seems to be entirely confined to the villagers.

Bitter flavour is sometimes alleged by the camp population as the reason why this salt is not used, but I am inclined to think that the dislike is more caused by prejudice against the source of the salt.

I have examined several specimens of earth salt, and found them to differ very widely in composition, some being of considerable purity, whilst others contained as little as 44 per cent of sodium chloride. In some cases I found that the fresh salt consisted of perfectly pure and white crystals of sodium chloride bathed in a mother-liquor of deliquescent calcium and magnesium salts, principally nitrates with some chlorides and sulphates. Either washed with cold water and then dried, or pressed between folds of blotting paper, the crystals were much purer and whiter than any sea-salt; but before this cleansing, a distinctly bitter flavour was imparted by the mother-liquor.

One specimen was brought to me by a man who engaged largely in the manufacture, as a fair specimen of the salt produced in his district. This I subjected to complete analysis. When air-dried it still contained 3 per cent of moisture; it was of slight alkaline reaction, clean, but of white effloresced appearance without any regular crystals. Exsiccated, it had the following composition per cent:—

Sodium chloride	44.50
Sodium sulphate	49.30
Magnesium sulphate	4.93
Magnesium nitrate	0.24
Magnesium carbonate	0.35
Calcium carbonate	0.70
Insoluble (sand, clay, &c.)	0.45

A person consuming daily the moderate amount of a quarter of an ounce of this salt would take along with the real salt a quantity of sodium and magnesium sulphates (anhydrous), equal to 121 grains of Glauber's salt, and 12 grains of Epsom salt. I do not think that difference of taste would warn people against this. Magnesium chloride, nitrate, and sulphate are very bitter, so also are calcium chloride and nitrate, and the presence of these in the mother-liquor adherent to crystals of salt would give a decided unpleasant flavour. This is not, however, the case with sodium sulphate; its taste is not very disagreeable, and in this sample it seemed to be entirely concealed by that of the chloride. A slightly bitter after-taste arose from the magnesium salts present.

The purification of the different samples of earth salt would have to be done in various ways, differing according to their respective composition. Those which consisted of pure salt coated with the deliquescent earthy nitrates and chlorides, could easily be purified by simple washing with a little cold water; but this would not do in the case of the sample containing a large quantity of sodium sulphate. If the quantity of sodium sulphate and other foreign salts did not exceed one quarter, the best plan would be to lixiviate the salt gradually with an equal quantity of hot water. But when, as in the case of the above sample, the quantity of sodium sulphate amounts to fully one-half, the purification would be best done in the following manner. Wash the salt with a very small quantity of hot water to remove magnesian and other deliquescent salts; then, the salt having cooled, add to it an equal quantity of the coldest water; the sodium chloride will dissolve to the extent of 40 parts in 100 of water, whilst the sodium sulphate will dissolve much more slowly and in a quantity inversely proportionate to the coldness of the water. 100 parts of water take up 10 parts at 60° F., 15 parts at 68°, and 20 parts at 77°. The colder the water the less sodium sulphate will be taken up; the residue will consist entirely of this salt, whilst the chloride can be recovered by boiling, in a much purer condition. The residue might possibly be utilised for the manufacture of carbonate of soda by calcination with kunkur and charcoal.*

The brackishness imparted by this salt to many of the wells sunk in the black cotton soil is different in character from that arising in consequence of "previous sewage contamination." In Bangalore, where, owing to the porousness of the soil, whole districts of the station are saturated with the mineral products of excrementitious infiltration, the salts found are quite distinct; sodium chloride, earthy (calcium and magnesium) chlorides and nitrates appeared in quantities varying from 50 to 300 centigrammes per litre, but I never found the slightest increase in the small amount of sulphates normal in the Bangalore subsoil water. Whatever the character of the water they always remained low—about 0.4 to 0.6 centigramme per litre. In Bellary, out of the influence of the black cotton soil, the subsoil water does not differ materially from that of Bangalore, and like it, contains a very small proportion of sulphuric acid; but the quantity of this constituent increases rapidly as the wells approach the black cotton soil—to 10 to 30 centigrammes are not uncommon, and one well yielded as much as 153 centigrammes (equal to 227 centigrammes per litre, or 159 grains per gallon of sodium sulphate).

The sulphates are accompanied by a proportionate quantity of chlorides, and invariably by some nitrates. The latter are in lesser proportion, as it is not usual in the water of uncontaminated soils for the amount to exceed 2 centigrammes per litre. These saline waters are not very hard, the greater part of the salts being alkaline (sodic) rather than earthy. Sodium chloride and sulphate are

the principal salts present, earthy chlorides, sulphates, and nitrates, being in considerably smaller proportion. The distinguishing characters between these saline waters and waters charged with the mineral traces of sewage may be thus tabulated:—

Saline Water from Black Cotton Soil.	Saline Water from Polluted Soil.
Much chlorine—	Much chlorine—
40-100 c.grm. per litre.	20-120 c.grm. per litre.
Much sulphuric acid—	Little sulphuric acid—
10-150 c.grm. per litre.	Under 1 c.grm. per litre.
Nitric acid variable—	Nitric acid large if not exposed to air and vegetation—
1-5 c.grm. per litre (rarely more).	10-30 c.grm. per litre.
"Permanent" earthy salts present; never greater than "removable" earthy salts.*	Very much permanent earthy salts; generally largely in excess of removable earthy salts.

In many cases the liquor extracted by the salt makers from the black cotton soil approaches very closely to sea-water in its composition, only differing materially by the presence of nitrates; the product of evaporation is hardly distinguishable from bay salt. The occurrence of sodium sulphate would seem to distinguish the mixture of salts from that found in sea-water, as that substance does not exist in sea-water; but its presence in earth washings is readily explained when we remember that any sodium silicate or carbonate existing in the soil would decompose the earthy sulphates of marine origin; insoluble earthy silicates or carbonates and soluble sodium sulphate being the result. And it is to be remarked that the soils which produce salt do not produce soda, the presence of the earthy sulphates that accompany the salt preventing apparently the soda being produced as it otherwise would be.

A peculiarity of the marine deposits (as I believe they are) diffused through the black cotton soil country is their tendency to accumulate in the lines of drainage; not only about dry watercourses at the low level of valleys, but also nearer to the larger drainage system of the country. I am informed that, in some parts of the Ceded Districts, wells near to rivers give, as a rule, brackish water, quite contrarily to what one would expect. The reason of this is probably to be found in the very partial washing which the soil undergoes from the scanty rainfall. The salts are washed from the soil of the higher tracts of country, but by the time the subsoil drainage water has percolated to the lower parts of the valleys, it is much nearer to the surface and the cessation of rain with the force of evaporation causes the salts to stop on their journey towards the sea.

In connection with this subject two points may be noted:—

(1). These sulphated waters readily evolve sulphuretted hydrogen when in contact with wood. Sojourn in a tub for one night causes most Bellary water to smell offensively by the next morning. This should not be confounded with "putridity," as it too often is in sanitary documents.

(2). The sulphates and chlorides appear to be inimical to vegetable life when repeated irrigation has caused garden soil to become charged with these salts; but in more moderate quantity the sulphates have a beneficial effect on plants requiring much sulphur, leguminous and cruciferous plants for instance. Bellary onions are well known for their excellence and abundance; it is possible that they flourish in consequence of being so freely supplied with the sulphur necessary for the formation of their essential oil.

* One cannot, however, but be astonished that the manufacture of this culinary salt should be continued, in spite of its impurity and the small pecuniary advantage in its use, now that the railway passes through the Ceded Districts. I believe that Government loses a large amount of revenue owing to the substitution of this earth salt for sea salt.

* I use these terms derived from the soap-test purely for convenience, meaning by "removable" earthy salts the carbonates and silicates of calcium and magnesium correctly ascertained. Boiling does not remove them, however; a water may be entirely free from "permanent" earthy salts (chlorides, sulphates, nitrates), yet show after boiling considerable permanent hardness. Evaporation to dryness and re-solution, give far more correct results.

Nitre.

Nitrates are invariably found in well-waters derived from subsoils of decomposed felspar or of clay. Ammonia, whether that normally found in the atmosphere, or that produced by organic decay, becomes oxidised when in contact with porous soil, and in presence of bases with weak acids—such as silicates and carbonates—it changes into nitric acid, and expels the weaker acid. As there are few soils that do not contain silicates and carbonates of either potassium, sodium, magnesium, or calcium the presence of nitrates is nearly universal, and we would naturally expect to find them in the washings of the salt-mounds. The filtration of water through soil containing silicates or carbonates would generate nitrates even if none were present originally. I found as much as 1.5 per cent of nitric acid in the solid residue of a sample of earth washings, a quantity equal to 176 centigrammes per litre of the fluid; and the moisture adhering to the crystals of salts subsequently obtained was highly nitrous. The nitrates present in the earth-washings are always the deliquescent nitrates of calcium and magnesium; the sodium salt being excluded in consequence of earthy sulphates and chlorides having already decomposed any sodium silicate or carbonate that would otherwise have been available for the saturation of nitric acid as it is formed. Potassium being comparatively of rare occurrence in these soils is excluded also from combination as nitrate. The nitrates existing in every sample of earth-washings that I have examined are consequently wasted; while if the mother-liquor of the salt crystals were treated with wood ashes, or other convenient source of potash, the earthy metals would be replaced by potassium, and nitre would be obtained. The quantity, would, it is true, be not more than 2 or 3 per cent of the common salt obtained.

The nearest place where I could find nitre to be regularly made was at Sirragirri, about 20 miles north of Bellary. From the account given me of the process by the nitre maker of Sirragirri, it would appear that earthy nitrates are never utilised, and that soil containing potassium nitrate already formed is the only kind worked. To obtain nitre at once in this condition, in a country where potassium salts are rare in the soil,* the nitre maker must confine his operations to soils in the neighbourhood of villages, selecting those spots where, from infiltration of urine, from the drainage of cattle sheds, or from the vicinity of ash heaps, the earth has become artificially supplied with potash. Considering that Indians generally use the manufacturing processes which are best adapted to circumstances, and which, though rude, are quite as profitable to them as the more ingenious but more expensive processes of European industry, I am rather surprised that the addition of potash to earth-washings containing earthy nitrates is not practised in India as it is in Europe. The earth-washings are allowed to evaporate as in the manufacture of salt, and any earthy nitrates are lost in the mother-liquor. The nitre is obtained tolerably clean, in small prismatic crystals mixed with the cubic crystals of common salt; this impurity varies from 6 to 20 per cent, or more. If required refined, it is purified by solution and re-crystallisation, a most wasteful process under the circumstances, as about 30 per cent of the nitre is lost.

The impure nitre is sold at one rupee per maund of 24 lbs.; when purified, the same quantity costs one rupee twelve annas. This very low price is, I think, occasioned by the nitre being too impure for shipment, and the manufacturers are not acquainted with the processes of refining economically. The nitre might be bought and refined at a total cost of not more than 12s. per cwt., it being worth 28s. to 30s. at home. Ignorance of economical refining processes affords the only explanation of the low prices obtained for an article of such value. To refine it

* The greater part of the soil of India is produced by decomposition of metamorphic rocks,—gneiss, basalt, trap,—the felspar contained in these are principally soda felspars.

economically it would be necessary to accumulate a large quantity; mix it well, and determine from an analysis of a sample the process to be adopted for its purification. The process applicable to a nitre containing only 5 per cent of impurity would be quite inapplicable to another sample containing 40 per cent of impurity.

Soda.

I have not been able to meet with any instance of this salt being produced near Bellary; that sold in the Ceded Districts is made, I believe, near Cuddapah. The sodium carbonate, of which the impure soda principally consists, is the result of the decomposition of sodium silicate by atmospheric carbonic acid. Silicic and carbonic acids are about of equal strength, and it entirely depends on circumstances which acid can expel the other from its combinations. Silicic acid expels carbonic acid from solutions, whilst carbonic acid acting in excess, and for long periods of time, expels silicic acid from solid silicates. In parts where the soda is produced it is found principally as an efflorescence on the surface, the sodium silicate of the soil having evidently been decomposed by atmospheric carbonic acid. Its presence is incompatible with that of earthy chlorides, sulphates and nitrates; and as these are constantly found accompanying the salt and nitre yielded by black cotton soil, it is evident that the production of salt or nitre excludes that of soda.

Natural sodium carbonate does not appear to be produced in India to any considerable extent, perhaps little in excess of the limited requirements of washermen.*

The main features of the production of these earth salts may be thus summarised:—

Salt is derived from marine deposits in the black cotton soil. It may be mixed with the following impurities:—

- (1). Marine earthy salts, principally magnesium chloride and sulphate.
- (2). Sodium sulphate, produced by the decomposition of marine sulphates by sodium silicate.
- (3). Nitrates, principally of magnesium and calcium.

Nitre does not accompany salt as such (as potash nitre), but indirectly as earthy nitrates. Potash nitre can only be obtained from soils to which potassium salts have been added accidentally or purposely. Soils containing the nitrified products of decayed animal matters are alone profitable to work; even in these there is great loss unless potassium salts be added.

Soda is produced in soils by the action of carbonic acid on the sodium silicate of decomposed felspar rocks. Both the carbonate and the silicate of sodium being decomposed by the soluble earthy salts which invariably accompany salt and nitre, soils yielding the latter salts cannot yield soda.

FLUORESCENT RELATIONS OF ANTHRACENE AND CHRYSOGEN.

By HENRY MORTON, Ph.D.,
President of the Stevens Institute of Technology.

In the course of an investigation of the fluorescent spectra of certain organic and inorganic substances, some of the results of which have just been anticipated by Becquerel in a memoir presented to the French Academy (see *Comptes Rendus*, vol. lxxv., p. 296), I was led to study pretty thoroughly the properties of anthracene in this connection, and have arrived at certain results which are new, and possibly of some moment in their bearing upon

* For many years there has been advertised a machine warranted to produce ice by the aid of two salts indigenous to India, and procurable everywhere at a cheap rate. The two salts are sal-ammoniac and carbonate of soda. Most possessors of these frigatefactive engines can give doleful accounts of their searches in the bazar after the last named salt.

the discrimination between that substance and some of the associated bodies.

In the first place, it should be noticed that anthracene is ordinarily procurable in several forms, either as—(1) a dark olive-green crystalline fused mass or (2) a green-grey powder, both these being its crude state; (3) as a light brown flaky powder, in which form it is imported from the best German chemical manufacturers under the title of chemically pure anthracene; (4) as a snow-like powder with a faint yellow tinge, in which condition it can readily be obtained by distillation in a current of air; or (5), lastly, as a mass of pearly scales, also with a tinge of yellow, in which form it is readily obtained by crystallisation on cooling from a solution in alcohol saturated at the boiling-point.

In any of these forms, when placed in the path of a beam of sunlight (see Fig. 1), condensed by a lens, and passed through a tank containing ammonio-sulphate of

FIG. 1.

copper in solution, and then examined by a spectroscope, anthracene yields a spectrum (of which Fig. 2 is a rough drawing) consisting of four bright bands, separated by dimmer, but not absolutely dark, spaces. The first of these bands is of red colour, the second of orange and yellow, and the other two green.

The dark space dividing the red from the orange is narrow and faint compared with the others, which, even in the lightest form of the material, as mentioned above, are strongly marked. The striking persistence of this fluorescent spectrum, in face of the great change in optical appearance of the substance itself, is curious, and furnishes a ready means of recognising this body under the endless variety of tints and structural conditions which it assumes.

In his admirable work, entitled "La Lumiere" (vol. i., p. 382), Becquerel notices, among other "phosphorescent" bodies, an "hydrocarbon having the colour of the uranium salts, and obtained from Fritzsche." He also gives the spectrum of this substance, as seen when "excited" in his phosphorscope. No measurements are furnished, but the bands are shown in their relation to the Fraunhofer lines, and in this regard the correspondence with the spectrum shown in Fig. 1 is so close that I should have little hesitation from this alone in believing that Becquerel's hydrocarbon was anthracene; but when it is remembered that anthracene, under the name of photene, was first studied by Fritzsche, the inference becomes much stronger.

While writing the above, I received the last number of *Poggendorff's Annalen* (1872, No. 7), and there find the remarks by E. Hagenbach on the above subject, in which he states that his examination of a minute fragment of photene or anthracene obtained from Wöhler leads him to the conclusion that it differs from that used by Becquerel.

As, however, I find a perfect agreement in the position of these bands in specimens of anthracene obtained from several foreign and American sources, and in all sorts of conditions resulting from various treatment, it seems to me clear that Becquerel's material is identical with what is now known in commerce as anthracene.

We naturally inquire, in the next place, whether this spectrum is due to pure anthracene or to some intimately associated impurity. To settle this it was necessary to obtain some chemically pure anthracene.

After many trials, I found that, among all the processes recommended by Kopp in his excellent article in the *Moniteur Scientifique-Quesneville* (1871, p. 536), none would produce a body pure enough to bear this delicate optical test, except that of exposing the hot solution to sunlight. I, however, used the solution in alcohol with, I think, better results than benzene, which is recommended by him, as in this case no notable amount of paranthracene was formed. The substance thus obtained yielded a pretty blue fluorescence, but one much less brilliant than that of the partially pure variety, and this, when examined with the spectroscop, showed a continuous spectrum.

In all its general properties, this substance agreed with that prepared by distillation and repeated crystal-

FIG. 2.

lisation from hot alcohol, being like it made up of pearly-white scales, reacting chemically as pure anthracene should. In fact, the two forms are not to be distinguished except by this optical test.

It can therefore, I think, be safely concluded that pure anthracene does not give a banded spectrum by fluorescence, and that the spectra given by Becquerel and Hagenbach, as well as that shown in Fig. 1, belong to some associated body.

Before leaving this part of the subject, I would remark that, if a solution of anthracene in hot alcohol is allowed to cool to about 80° F., it will deposit a crop of crystals, which seem to carry down nearly all the fluorescent colouring matter, so that those deposited by cooling it further to 32° F. will be far lighter. The special state of aggregation also has a marked effect upon the intensity of the fluorescence; the flakes deposited from a solution in cooling, or the crystals obtained by evaporation, being much more active in this respect than those obtained by distillation, or rather sublimation. A white powder, obtained by adding water to the alcoholic solution, has also in some cases no easily appreciable fluorescence, and the first specimen which I prepared by exposure to sunlight had so little fluorescence that I described it at first as equal only to that shown by white paper. Other specimens, however, similarly prepared, gave the delicate blue fluorescence above mentioned.

Considering, next, what was the origin of the fluorescent light which gave the banded spectrum, we find that Fritzsche gives the name chrysogen to a yellow substance accompanying anthracene, which is soluble in ether, is destroyed by exposure of its hot benzole solution to sunlight, and of which a quantity too small for analysis was isolated by him (*Comptes Rendus*, vol. liv., p. 610).

This is, without doubt, the substance whose spectrum is found in all the forms of anthracene first enumerated, and in the material examined by Becquerel.

In addition to the fluorescent spectrum furnished by impure anthracene, or rather, we should say, chrysogen, it gives a very characteristic absorption-spectrum, showing two strongly-marked bands, a less defined one, and a total extinction of all rays above 13.8 (see Fig. 3).

To obtain this, it is best to distil some of the crude green anthracene in a current of air (see CHEMICAL NEWS, vol. xxv., p. 165) at a rather high temperature, so as to get a yellow product, then to wash this thoroughly with cold alcohol, which removes a brownish yellow material, yielding no absorption-bands, and little, if at all, fluorescent.

The material now left may be spread on filter-paper and examined by transmitted blue light, as shown in Fig. 4; or it may be mixed with melted paraffin and

FIG. 3.

FIG. 4.

spread on glass, or fused between slips of mica or glass, and examined in the same way. The absorption-spectrum shown in Fig. 2 is then seen.

The band near 9 of scale, or Fraunhofer's line F, encroaches on the upper bright band of the fluorescent spectrum, so that in certain methods of observation, when absorption and fluorescence are observed at once, this bright band seems to be narrower than the one next below, which, however, is not the case in fact.

The band about 13 of the scale, or Fraunhofer's line G, is not well defined, and is connected by a shade with the point about 14, where the absorption becomes total.

The imported chemically pure (?) anthracene, washed

FIG. 5.

FIG. 6.

with alcohol to remove the above mentioned brown matter answers very well for this observation.

If either of the above two last forms of anthracene are dissolved in benzole (coal-tar naphtha) a yellowish solution is obtained, which fluoresces with a brilliant green colour and gives the spectrum shown in Fig. 5, which it will be seen by comparison with Fig. 1 differs from that of the solid substance only in the displacement of all the bands

towards the violet end of the spectrum. The same holds good with the absorption-bands, as will be seen by comparing Fig. 6, which shows the absorption spectrum of a solution of impure anthracene (*i.e.*, chrysogen) in Benzole.

This is an action which has never, I believe, been observed before. I have a partial parallel found in a few of the uranium salts which I have examined with this view, but it is not noted by Stokes, Becquerel, or Hagenbach.*

It does not, however, stand alone. Some months since, in a Paper read before the American Institute in New York, and the Franklin Institute Philadelphia (see *Journal of the Franklin Institute* vol. lxiii., p. 296), I announced under the name Viridin a solid substance of remarkable fluorescent properties, and yielding a spectrum closely allied to that of anthracene.

Subsequent experiment has confirmed these results, and has also demonstrated that, like ordinary anthracene, this substance is a mixture of a coloured body yielding a banded spectrum, which, to avoid circumlocution, I would call Thallene, in allusion to the bright green bands of its fluorescent spectrum, as well as to the general character of its fluorescent light; and a white body crystallising in spicules, which I would call Petrollucene, in allusion to its origin, fluorescence, and resemblance to anthracene, from which it differs, however, in crystalline form, melting-point (this being in its case about 700° F.), and in solubility.

With this mixed body, as with the anthracene above described, the spectrum of fluorescence, as also that of absorption, has all its bands displaced towards the more refrangible part of the spectrum, without other change by solution in various solvents.

In the case of the oxalate of uranium the *absorption-bands* are displaced downwards in the spectrum by solution. When a pure spectrum is thrown on a screen covered with either of the above mentioned hydrocarbons or on a tank filled with their solution, a series of maxima and minima of fluorescence are observed which in each case coincide with the absorption-bands of the same body, a maximum of fluorescence coinciding with a maximum of absorption. A relation similar to this was pointed out by Stokes in the case of leaf-green solution, *Phil. Trans.* 1852, Part II., p. 491, and in canary glass and uranium nitrate in a general way, *Phil. Trans.* 1852, Part II., p. 497, and p. 517. Hagenbach has also noticed this relation in a number of the substances which he has examined, and also points out the *absence* of any connection between the numerous absorption-bands seen in nitrate of uranium and the fluorescent maximum of that body.

In conclusion I have to thank my friend Dr. G. F. Barker for valuable aid through his familiarity with the chemical literature of the day, and for aiding me in obtaining a fresh supply of the new material when a difficulty in this direction had arisen; also to Mr. John Truax, of Pittsburgh, in the same connection, also to Mr. J. C. F. Chever, the Superintendent of the works of Messrs. Page, Kidder, and Fletcher, at Bull's Ferry, N.J., for some specimens of unusually fine crude anthracene prepared at those works, from which most of my preparations of that body have been made. Also my assistant, Mr. W. E. Geyer, and Messrs. P. P. Poinier and A. H. G. Sorge, students in the Institute, for various assistance in connection with these observations.

* After the above was written and had been published in the *American Chemist* of September for some weeks I received *Poggendorff's Annalen* in which I find that Hagenbach had just noticed a similar action in a few bodies dissolved in different menstrua.

CORRESPONDENCE.

THE UTILITY OF ODOURS TO PLANTS IN
RELATION TO RADIANT HEAT.*To the Editor of the Chemical News.*

SIR—The more closely and philosophically the works of Nature are studied, the stronger, generally speaking, is the conviction that, in every department of them, a principle of utility has been strictly and uniformly kept in view, and that accordingly, where the enquirer might least expect to discover it, this principle may often be indisputably traced.

A very apposite and striking illustration of this scientific truth is found, I think, in the relation of the odours of flowers, and of other fragrant organs of plants, to radiant heat; and as the subject is one which has not hitherto, I believe, been especially noticed, I may perhaps be permitted to draw attention to it in your valuable pages. In order, however, that these brief remarks may be fully understood, it is necessary to refer to the important and interesting discoveries of Prof. Tyndall, in thermal radiation, a *résumé* of which he delivered before the University of Cambridge, in the Rede Lecture for 1865.

He found then that odours or perfumes, in common with many gases and vapours, especially that of water, have the remarkable property of absorbing large quantities of radiant heat, and particularly the obscure or non-luminous rays, such as those emitted by the earth. Thus he has shown, in his table of the "Absorption of Perfumes," that otto of roses absorbs 37 times as much radiant heat as perfectly dry air, the oil of lavender 60 times as much, that of rosemary 74 times as much, while that of aniseed absorbs no less than 372 times as much.

And, turning from perfumes to vapours, he observes, "that probably from 10 to 15 per cent of the heat radiated by the earth is absorbed within 10 feet of the earth's surface," although the aqueous vapour contained in the atmosphere amounts to only $\frac{1}{4}$ per cent of the whole mass of the air. This aqueous vapour, thus becoming heated, "wraps," as he says, "the earth like a warm garment, and protects it from the deadly chill it would otherwise sustain;" for it must be remembered that radiation and absorption always correspond, and that, accordingly, in the case of gases and vapours, the best absorbers are, at the same time, the best radiators. The same remark applies equally to odours or perfumes; and thus we are brought back to the especial subject of these observations.

Let us, then, consider the case of a tender plant, such as a rose in a healthy growing state, and emitting copiously from its lovely blossoms the unrivalled essential oil to which it owes its fragrance, and let us ask—What is the office which, quite independently of the assumed very subordinate one of regaling the olfactory sense in man, this plentiful and continual discharge of aromatic matter into the atmosphere is intended to fulfil? The answer to this question follows naturally, I think, from the preceding facts; for if, as Prof. Tyndall has proved, the odour of the oil of roses absorbs 37 times more radiant heat than dry air, and radiates in the like degree, we may confidently infer that the plant, in thus generating around it a warm atmosphere of odour, is ministering to its wants by virtually providing for itself a more congenial temperature than it could otherwise enjoy. And if we pass from individual instances, and consider generally that the flowers of plants are especially the seat of the odours they emit,—and, moreover, that the production of seed is essentially dependent upon the flowers, not only physiologically, but in all their physical relations, particularly that of temperature,—we cannot fail, I think, to conclude that the envelopes of aroma, if I may so speak, which surround the flowers must materially aid in the maturation and protection of the seed.

Many fruits also, such as the lemon and orange, so remarkable for their fragrance, may have their ripening hastened by the essential oil that they so freely give forth; this oil, in the case of the lemon, absorbing, according to Prof. Tyndall's experiments, 65 times as much radiant heat as dry air.

Even, too, in the case of some of the flowerless plants, the ferns for example, the odour that the fronds exhale, and which is very characteristic in this numerous and interesting order, may serve as a protection against cold, and thus also indirectly aid the fertilisation of the spores.

It would be easy to present further illustrations of the views which, in a very imperfect form, I have submitted to your readers; but having, I fear, already trespassed upon your columns, I must leave them to follow out the subject in all its instructive and important relations.—I am, &c.,

W. H. OLLEY.

Stoke Newington.

CONSTITUTION OF MATTER.

To the Editor of the Chemical News.

SIR,—I beg to express my thanks to your correspondent, J. W., for pointing out the inaccuracy of two statements in my paper. Both were clerical errors:—Methyl should have been written $(CH_3)_2$, not CH_3 , and "propionic aldehyd" should have been substituted for "propylic alcohol."

But the two particular cases of isomerism that I cited are not necessary to substantiate my illustrations of the oneness of matter; others would do as well. It is evident that Mr. Sutton has confounded matter and force in several instances; but let us proceed to examine his objections to my arguments. He considers the analogous properties of chlorine, bromine, and iodine, and other groups of bodies, to constitute no proof of the mono-elemental theory. If it is not a proof, it is at least an argument in its favour; and if I can show that the atomic theory supports the mono-elemental one, it will be almost a proof under Mr. Sutton's view of matter, for he says the atomic theory is opposed to unity of matter. Now Mr. S.'s view is embraced in the following passage:—"We have no doubt that the only difference between the so-called elements (hydrogen, oxygen, &c.) is the difference of their respective atomic weights, and of course corresponding atomic sizes;" but nickel and cobalt have the same atomic weights and sizes,—therefore there is no difference between the two, so that nickel is cobalt and cobalt is nickel, and yet Mr. Sutton argues that in their natures they are different. It really seems as though he were ignorant of the existence of groups which, regarded under his favourite theory, viz., the atomic theory, are isometric,—that is, have the same atomic weights and sizes or volumes.

Mr. Sutton next writes—"And if this is the case, the ultimate atoms themselves (whether of hydrogen, oxygen, or any other element) must be all of the same and only elemental matter, because, not being themselves composed of atoms, no difference in the nature of their substance can exist." The meaning of this is apparently "buried" in "profound obscurity;"—if atoms are not composed of atoms, what are they composed of?

I confess I fail to see into what error Mr. Sutton affirms I have fallen, but it is obvious that he has made a serious error by saying "the withdrawal of the forces cannot alter the atomic sizes." If this be a fact it is most important, but I am unwilling to accept it as such until I know by what experiments or reasoning he has demonstrated it. Would it not be wiser to say the atomic size is an effect of force? For if it is not, then the atomic volume of water at 100° C. would be the same as at 0° C.—yet even Mr. Sutton would see the untruth of this. Again, if "the withdrawal of the forces cannot alter the atomic sizes," why should the atomic volume of any one

element or body be different from that of any other? Or (to view the matter in another light) if matter cannot exist without force, then force must exert an influence over matter under any circumstances,—therefore the size or volume of atoms is influenced by force.

Your correspondent is apparently delighted to find a lack of faith on my part in what he is pleased to call "my philosophy," which includes the belief that a "compound is formed by a uniting force between two or more such differently operated upon portions of elemental matter," because I confess that in potassic iodide the iodine exists in its own nature. Does not Mr. Sutton see that the whole gist of my paper was to prove that iodine in its nature is the same as hydrogen, or any other so-called element, the different properties arising from each of the different portions of elemental matter being influenced by the forces in peculiar ways? and, if so, where has he discovered my lack of faith? The fact is that he based all his arguments upon atomic volumes and weights, which subject in his hands, as opposed to the mono-elemental theory, entirely broke down, and, as a necessary consequence, the arguments founded upon it.—I am, &c.,

CHAS. T. KINGZETT.

Liverpool, October 16, 1872.

ITALIAN CHEMICAL MANUALS.

To the Editor of the Chemical News.

SIR,—The statement recently circulated as to the non-existence of chemical manuals in the Italian language is incorrect, as the following list of such works amply proves.—I am, &c.,

A. H. C.

- PIRIA, R., "Lezioni Elementari di Chimica Organica." Turin, 1870.
TASSINARI, P., "Avviamento allo Studio della Chimica." Pisa and Turin.
TASSINARI, P., "Manuale di Chimica Inorganica." Pisa.
OROSI, "Manuale di Chimica Analitica Inorganica." 1871.
SCIVOLETO, P., "Principi di Chimica Analitica." Naples, 1869.
SELMI, A., "Chimica applicata all' Agricoltura." Milan, 1871.
MANCUSO, G., "Trattato di Chimica Generale e Descrittiva." Palermo, 1872.
ANTONELLI, "Trattato di Chimica Moderne." Modena, 1865.
BOUZANI, F., "Elementi di Chimica Inorganica." Savona.
CHURCH, A. H., "Guida al Laboratorio." Venice, 1872.
CARLEVARIS, P., "Trattato di Chimica." Turin, 1870.

TESSARI, N., "Compendio di Chimica Generale." Rovereto.

MODIFICATION OF MOHR'S BURETTE.

To the Editor of the Chemical News.

SIR,—I observe in your last issue a paper on "A Simple Modification of Mohr's Burette, to adapt it to all Test-Liquids," as suggested by Capt. Heriot and Mr. R. Biggs. Allow me to refer those gentlemen to a communication made by me to the Bristol Naturalists' Association, in February, 1864, and reported in the CHEMICAL NEWS, vol. ix., p. 94, in which I described and exhibited an instrument precisely similar to theirs, and claimed for it the obvious advantages mentioned in the more recent paper.

I have had the instrument I then exhibited in frequent use since, but have recently discarded that and all other forms of burette in favour of the glass stop-cock modification, which is now made to perfection, is but slightly more expensive than the other sorts, and leaves nothing

to be desired for ease and precision in manipulation.—I am, &c.,

EDWARD COLLENS.

Birmingham Vinegar Brewery,
October 23, 1872.

[In reference to this form of burette, another correspondent says that a similar one was used in Mr. Vernon Harcourt's and Mr. Esson's elaborate investigation into the laws of the rate of chemical change, at the Oxford University Laboratory. He calls our attention to one or two serious defects of the arrangement, which have more than once tempted him to abandon it for the glass stop-cock:—(1). Any change of temperature either expands the air above the fluid, and causes loss or excessive delivery, or else causes contraction, and rise of air into the beak, with consequent raising of the level of the liquid in the burette. In the latter case any attempt at adjustment is almost always accompanied with loss of fluid. (2). It is next to impossible to deliver single drops by the arrangement, unless the beak is so contracted as to give nothing else,—a state of things obviously inconvenient. (3). Leakage is always occurring at the cork, so that air is admitted above, under the strong pressure of the long column of fluid contained by the burette when full.—Ed. C. N.]

MISCELLANEOUS.

Salles du Progrès, Soirées et Matinées de Science Illustrée.—The Abbé Moigno has forwarded to us the comprehensive programme of a plan devised by him, the arrangements for which are now completed, to give popular instruction, varied by recreative musical and physico-chemical, optical, and other experiments and exhibitions, for the purpose, in the first place, of aiding the education of a large class of people in Paris who now spend too much of their time in frequenting cafés, chantants, and other places of amusement of a questionable character; and also of affording instruction to young men in science in its widest sense, inclusive of art and applied science. The Abbé Moigno considers that ignorance is at the bottom of the many evils and dangers of his country; and in order to instruct and elevate the mind, he has spared no pains or expense to render his Salles du Progrès attractive as well as useful, by judiciously combining the *utile dulci*. We sincerely wish him success, and trust that the institution may prove a real boon to that country of which we hope will be verified in more than one sense the *fluctuat nec mergitur* of the Parisian coat of arms, because—La France intelligente éclairée et libérale ne périt pas.

Quality of the Gas of London.—Dr. Letheby, the Chief Gas Examiner appointed by the Board of Trade, has recently reported to the Corporation of London, and the Metropolitan Board of Works, on the quality of the gas supplied by certain of the Gas Companies during the quarter which has just expired; from which it appears that the average illuminating power of the Chartered Gas has been as follows:—17.39 standard sperm candles at Becton; 17.01 at Cannon Street; 17.45 at Friendly Place, Mile End; 17.96 at Arundel Street; and at Millbank 17.35. That of the Imperial Company has been, 17.46 candles at Oakley Square, Chelsea; 15.85 at Camden Street, Camden Road; and 16.59 at Graham Road, Dalston; while that of the South Metropolitan Gas Company at Hill Street, Peckham, has been 15.71 candles. The average illuminating power of the canal gas supplied by the Chartered Company has been equal to 25.12 standard sperm candles at Arundel Street, Haymarket; and 27.10 candles at Millbank. With regard to purity, Dr. Letheby reports that the gas at all the testing places has been, except on two occasions, constantly free from sulphuretted hydrogen. The two occasions referred to were the 3rd of August and the 26th of September, when the gas of the South Metropolitan Company at Hill Street, Peck-

ham, contained traces of this impurity, which he ascertained were due to unavoidable circumstances. The amounts of sulphur in other forms than this have averaged in the case of the Chartered Company's common gas, 11.19 grs. per 100 cubic feet at Beckton; 10.50 grs. at Cannon Street; 6.36 grs. at Friendly Place; 9.94 grs. at Arundel Street; and 23.37 grs. at Millbank. In that of the Imperial Company it has averaged 32.64 grs. at Oakley Square; 26.74 grs. at Camden Street; and 27.68 grs. at Graham Road. The amount of sulphur in the South Metropolitan gas has averaged as much as 33.4 grs. per 100 cubic feet. The average amount of this impurity in the canal gas of the Chartered Company has been 15 grs. at Millbank, and 25.36 grs. at Arundel Street. It appears that, with one day's exception, the proportion of sulphur in the common gas of the Chartered Company at four of the testing places—viz., at Beckton; at Friendly Place, Mile End; at Cannon Street; and at Arundel Street—has not exceeded 20 grs. per 100 cubic feet during the whole quarter; and for the last two months it has not exceeded 15 grs. per 100 feet. This is very satisfactory, for it shows that with the care used at these works the proportion of sulphur can be kept under 20 grs. per 100 feet. The quantity of ammonia in the gas of all the Companies has been at all times below the prescribed amount of 2.5 grs. per 100 cubic feet. Dr. Letheby has drawn the attention of the Corporation and the Metropolitan Board of Works to certain irregularities in the returns of their Gas Examiners, and has pointed out the necessity of fulfilling the obligations of the several Acts of Parliament, which are in the interests of the public.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 14, 1872.

This number opens with a lengthy report by M. Tresca of the proceedings of the International Congress for Weights and Measures. The labours of the Congress are concluded.

New Process of Estimating Free Oxygen.—Schützenberger and Gérardin.—Hydrosulphite of soda, $S_2O_3Na_2OHO$, or, according to the new notation, SN_2OHO , differs from bisulphite of soda only by 2 equivalents or 1 atom of oxygen; in the presence of free oxygen, that gas is at once absorbed by the hydrosulphite, and instantaneously converted into bisulphite, $S_2O_3Na_2OHO + O = S_2O_4Na_2OHO$, or— $SN_2OHO + O = SON_2OHO$.

The solution of the hydrosulphite of soda is readily obtained by causing zinc scraps to act upon a solution of bisulphite of soda (sp. gr. at 15° , 1.162) in a closed bottle for some twenty to twenty-five minutes; this solution is used to absorb oxygen gas, and has the advantage of not soiling the test-tubes like pyrogallate of potassa. The solution is also applied by the authors to test the presence and estimate the quantity of free oxygen dissolved in water, which is first tinged with Couper's soluble aniline blue, a compound which is instantly decolorized by the hydrosulphite of soda, but is not acted upon by the bisulphite of that alkali; the solution of hydrosulphite is then added until decoloration takes place. As this reagent is prone to decomposition, it is titrated. The authors having found that the hydrosulphite decolorises a solution of ammoniacal sulphate of copper, while the sulphite and bisulphite of soda do not act upon it so long as ammonia is in excess, a strongly ammoniacal solution of that salt is so made that 10 c.c. of the fluid contain a quantity of copper corresponding, as regards the action of the hydrosulphite, to 1 c.c. of oxygen. The operation is conducted as follows:—A bottle of a capacity of from 60 to 100 grms. is partly filled with water, and a spiral of sheet-zinc and some lumps of granulated zinc are added; 10 c.c. of the solution of bisulphite of soda are then added, and the bottle next filled with water, and closed with a caoutchouc stopper. After having been shaken for a few moments, the vessel is allowed to stand for twenty minutes, and the reagent is ready. On the other hand, 20 c.c. of the

copper solution (ammoniacal sulphate) are poured into a test-glass, and some oil is poured on the surface. A litre of the water to be tested is poured into a large-sized beaker-glass, and coloured by means of a few drops of Couper's aniline blue, and some oil is also poured on its surface. With a graduated pipette, from 50 to 60 c.c. of the hydrosulphite solution are taken and poured gradually into the copper solution, taking care to stir it with a glass rod until decoloration takes place; next, with the same pipette, the hydrosulphite solution is poured gradually into the water also until decoloration takes place, care being taken in each case to hold the point. Supposing 17.5 c.c. of the hydrosulphite to have been used to decolorise the 20 c.c. of ammoniacal sulphate of copper, the quantity thereof corresponding to 2 c.c. of oxygen, and that, on the other hand, the litre of water has required 36.4 c.c. of the hydrosulphite solution, we put the following equation:—

$$17.5 : 2 = 36.4 : x = \frac{36.4 \times 2}{17.5} = 4.16 \text{ c.c. of oxygen dissolved in the water.}$$

Anti-Ferment Substances.—A. Petit.—This paper contains the record of some experiments made with the view to ascertain the effect of certain substances on a fermenting liquid made up of 50 grms. of sugar to the litre, and 0.5 grm. of dry yeast to 10 c.c. of fluid. It appears that when silicate of soda and borax are added to such a solution, these salts exert no marked anti-fermentative action. 1 per cent of a solution of sulphate of iron does not affect the fermentation; but it is arrested by a 1 per cent solution of sulphate of copper. Phosphorus, oil of turpentine, mustard-powder, creosote, sulphuric and tartaric acids, all in quantities of 1 per cent, fail to affect fermentation; while 1-100th of arsenious acid renders the action more slow, 1-300th of oxalic acid renders it still slower. Acetic acid does not appear to be an anti-ferment, and a liquid containing 25 per cent of alcohol, 5 per cent of glycerine, and 1 per cent of succinic acid, enters readily into fermentation; on the other hand, corrosive sublimate and red oxide of mercury are strong anti-ferments, even in very small quantities. Sulphites do not impede fermentation, and are converted into sulphates.

Sitzungsberichte der Mathematisch-Physikalischen Classe der Königlich Bayerischen Akademie der Wissenschaften zu München, No. 2, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Quantity of Ammonia Contained in Snow-Water.—Dr. Vogel.—This essay contains in the first place an excellent *résumé* of the labours of different savants on the presence of ammonia in the atmosphere and in arable soil, as well as in rain- and snow-water. The author refers to Dr. von Liebig's researches, made in 1826 and 1827, on the quantity of ammonia as nitrate in rain-water, and then records at length his own researches on the presence and quantity of ammonia contained in snow and in snow-water. The method employed by him in this instance is that of Schöbinger, somewhat modified, as applied to the estimation of ammonia in arable soil; the following results were obtained, 1 litre of the snow-water being the unit:—Freshly-fallen snow, collected in a porcelain basin, at 0° gave 0.003 grm.; at -3° gave 0.002; at from -9° to -15° gave 0. Snow-water, from snow which had lain for twenty-four hours on a piece of garden-ground manured during the previous autumn, contained 0.012 grm. Snow-water from snow which had been lying for twenty-four hours on a meadow contained 0.009. Snow (all of the same period of falling) which had been deposited for twenty-four hours on a zinc-covered roof contained 0.004. The author observes that the quantity of ammonia contained in snow depends upon a variety of conditions, and that since snow, owing to its porosity, absorbs ammonia, and the same obtains with the water formed from it, it is absolutely necessary to melt it in closed vessels. It appears that the quantity of ammonia contained in snow is also affected by the temperature at which it falls; at rather low temperatures (-15° , December, 1871) the author could not detect ammonia in such snow by Nessler's reagent for ammonia.

Photographic Effect (Licht Wirkung) of Various Coloured Leaves.—Dr. Vogel.—Notwithstanding the high scientific value of this memoir, its contents are not suited for abstraction.

Observations on Minerals Occcluded in Volcanic Rocks.—F. Sandberger.

Although not strictly belonging to chemistry, we quote the title of the following exhaustive memoir:—

Researches on Phyto-Electricity.—Dr. J. Ranke.

Preliminary Observations on Buchonite, a Kind of Rock Belonging to the Group of Nephelines.—F. Sandberger.—This memoir contains the exhaustive geognostico-mineralogical description of a new mineral discovered by the author in the Rhen mountains, Bavaria, and called by him Buchonite (from Buchonia, apparently the ancient Latin name for the Rhen district). The chemical composition of this mineral is, in 100 parts—Silica, 51.42; alumina, 15.39; protoxide of iron, 21.04; magnesia, 3.68; lime, 4.09; potassa, 1.07; soda, 2.37; water, 0.55; total, 99.61. A more complete analysis, including the undetermined small quantities of chlorine, phosphoric acid, titanic acid, and peroxide of iron, will be shortly published.

Spontaneous Decomposition of an Alloy of Lead.—Dr. Vogel.—It appears that among the collection of coins and medals belonging to the University of München there are preserved some copies of medals and coins made of a soft alloy—bismuth and lead—which was found to consist (when unaltered) of various proportions of the metals alluded to, viz.—(1). Lead, 66; bismuth, 34. (2). Lead, 86; bismuth, 14. (3). Lead, 88; bismuth, 12. It is apparent that these alloys were not

all made at the same time; in some instances the medals cast in these alloys had not only become somewhat oxidised but even quite fallen to powder, which effervesced on being treated with acetic acid, and the solution was found to contain chiefly lead, but bismuth was also present. The author observes that it is rather curious that alloys kept in well-closed show-cases should have become thus altered and deteriorated; the cause is ascribed to the tendency of bismuth to crystallise, whereby a molecular change is first effected, and thus oxidation is rendered more easy.

Les Mondes, October 17, 1872.

Inauguration of the Salle du Progrès.—Mazas de Sarrion.—The opening meeting of this institution was held on the 15th inst.; among the distinguished savants present we notice the following:—Dr. Otto Struve, director of the Imperial Russian observatory on the Pulkova, and President of the International Congress for Weights and Measures held at Paris; M. Broch, formerly Minister of Marine for Norway, and also a member of the Congress just-mentioned; the eminent botanist, M. Gay; and Professor Charles. The author speaks in high terms of the excellent plan of instruction adopted by the Rev. Abbé Moigno, and states that great satisfaction was felt by all present at the *tout ensemble* of the proceedings.

Disinfection and Collection of Fæcal Matters; Fahiman's System.—L. Crêteur.—The description of a mechanical contrivance applied to a closet, by the arrangement of which the fæcal gases are destroyed, the fæcal matter collected, and a rich manure produced; but nothing is said relating to the chemical and disinfecting methods applied.

Aurora Borealis, Thunderstorms, and Waterspouts.—Rev. Laborde.—This lengthy paper contains the author's views on these phenomena, which are explained by viewing our globe as a large-sized Leyden jar.

Journal de Pharmacie et de Chimie, October, 1872.

This number contains the following original papers relating to chemistry:—

Researches on the Gases Contained in the Blood.—Mathieu and Urbain.—By means of a series of experiments, conducted with peculiarly-constructed apparatus, the authors have made a chemical analysis of the gases contained in the blood taken from living animals kept at normal conditions of diet and mode of living. It appears that the proportion of gas contained in the arterial blood of an animal is the same when that animal is in the same condition; it further appears that the quantity of gases contained in the smaller arteries is less, in consequence of the smaller quantity of blood globules present in these vessels. As regards the respiratory action, the authors are inclined to think that endosmose and diffusion of gases play a very important part in that action.

Animal Charcoal and Phosphate of Lime.—M. Collas.—The author first observes that there is, as far as at least as decoloration is concerned, no necessity whatever to wash animal charcoal with dilute hydrochloric acid for the purpose of increasing thereby its decolorising property; he next observes that the hydrated phosphate of lime, the gelatinous precipitate caused by ammonia in an acid solution of bone-ash, has a powerful affinity for colouring matters, organic as well as inorganic, and that that substance by itself exerts a decolorising effect upon raw sugar. The conclusions drawn from these observations are that, far from being injurious, the phosphate of lime present in bone-black is really a useful ingredient, both on account of increasing the efficacy of the charcoal by rendering it more porous, and by acting as a decoloriser itself; bone-black should be washed with pure water before being used, and should be stored in cellars so as not to be exposed to direct sunlight.

Note on Testing Essential Oils for Adulteration with Alcohol.—M. Gault.—The essential oils, which are similar as regards their composition to the hydrocarbons ($C_{10}H_{18}$), are with difficulty dissolved in alcohol at 86 per cent applied in the proportion of 1 to 5. The essential oils containing oxygen, the composition of which is akin to aldehydes, and also such as contain sulphur, are more or less rapidly dissolved in alcohol of the same strength and applied in the same proportion; the mixture of these essential oils yields, even in the proportion of 1 to 10, a precipitate. If it is desired to make alcoholic solutions of essential oils—so-called essences—then the quantity of alcohol to be employed may be proportional to the degree of oxidation, the age, and the exposure to light and air of such oil.

Cultivation of the Cinchona Trees in Java.—M. van Gorkom.—In a letter to M. L. Soubeiran, the author states that the cultivation of these trees prospers in every respect; a manufactory has been established for the preparation of the spot of alkaloids, extracts, and other pharmaceutical preparations derived from the cinchona barks, and 6 tons of that bark were sold by public auction at Amsterdam in March last. The annual expenses of the cultivation, &c., are now balanced, and all the original outlay of capital is expected to be returned before the year 1876.

Neues Jahrbuch für Pharmacie und Verwandte Fächer, von Dr. F. Vorwerk, July, 1872.

In addition to original papers strictly belonging to pharmacy and pharmacognosy, this number contains the following original paper relating to chemistry:—

Metals Contained in Soot from Coals.—H. Reinsch.—The author states that, while testing some soot collected in a stove-pipe, he perceived the smell of arsenic; this gave rise to further experi-

ments, the result of which showed that the soot contained iron, manganese, copper, arsenic, potassa, soda, and lime, in rather considerable quantities. The coal which yielded this soot is that found at Zwickau, Saxony.

August, 1872.

This number contains no original papers relating to chemistry.

La Revue Scientifique de la France et de l'Etranger, September 28, 1872.

In addition to several original papers strictly belonging to physiology, topography, and medicine, this number (retarded in transmission) contains a report of the proceedings of the Chemical Section of the late meeting of the French Association at Bordeaux, from which we abstract the following:—

Chloride of Silver.—M. Stas.—When recently precipitated, this substance is soluble in water, 1 litre dissolving 13 m.grms. at the ordinary temperature, and 25 m.grms. at boiling temperature. These solutions are precipitated by hydrochloric acid, as well as by nitrate of silver; 1 molecule of the chloride of silver requires, for complete precipitation, 3 molecules of either the acid or the salt. Bromide of silver is completely insoluble in cold water, and only slightly soluble (2 m.grms. to the litre) in boiling water. When chloride of silver is dissolved in acetate of mercury, it requires for precipitation a quantity of hydrochloric acid or of nitrate of silver in the proportion of 3:1.

Analysis of Phosphates.—M. Prat.—The native phosphate is first acted upon by bisulphate of ammonia at a high temperature, and is next treated with cold water; carbonate of ammonia is then added to the decanted solution, whereby lime and alumina are precipitated quite free from phosphoric acid, which is left in the solution and estimated as metaphosphoric acid.

Ozone.—Liès-Bodart.—Experiments made by the author prove that, while albumen is not acted upon by ozone—retaining even the property of coagulating by heat—blood albumen, which in consequence of its colouring matter cannot be used in calico-printing, becomes quite decolorised by the action of ozone, leaving white and perfectly coagulable albumen. It further appears that ozone is a very powerful disinfectant, since the author found that a room, in which sulphurate of ammonium was purposely split, was readily disinfected by ozone.

Fulminating Compound.—M. Prat.—As a substitute for the fulminate of mercury in percussion caps, the author has used a mixture consisting of picrate of lead, chloride of potassa, and a very small quantity of amorphous phosphorus.

Hydrofluoric Acid.—M. Prat.—By causing phosphoric anhydride to act upon anhydrous hydrofluoric acid, the author obtained water and a non-condensable gaseous hydrofluoric acid, thus rendering it probable that the substance hitherto viewed as hydrofluoric acid contains oxygen; the non-condensable hydrofluoric acid still alluded to yields, by saturation with oxide of silver, a fluoride of silver resembling the chloride and quite different from the ordinary fluoride of silver. From these researches it would follow that the bodies known as fluorides, fluor-spar for instance, is, instead of fluoride of calcium, an oxyfluoride, and that the atomic weight of fluorine is wrong.

Abnormal Density of Perchloride of Phosphorus.—M. Wurtz.—The abnormal density (sp. gr.) of this body is stated to be due to its dissociation into free chlorine and protochloride of phosphorus. The author has made a series of careful experiments with the view of avoiding the dissociation and estimating the density of the perchloride, by operating in an atmosphere of the protochloride; while the theoretical density of the perchloride of phosphorus is 7.219, the author has found the following cyphers:—7.069, 7.687, 7.317, 7.255, 7.061, 6.975, 8.203, 6.806, 7.143, 6.785, 6.656. The figures most differing from the theoretical density have been found under special conditions, and depend upon the *rapport* of the volumes of the vapours of perchloride and protochloride of phosphorus; the very high figures belong to experiments in which the bulk of perchloride was very small, while in the case of the low figures the volume of the perchloride was in excess of that of the protochloride.

October 19, 1872.

This number does not contain any original papers relating to chemistry, but we call attention to—

Bibliography.—"Leçons Élémentaires de Chimie Appliquée aux Arts Industriels," par M. J. Girardin, Correspondant de l'Institut; cinquième édition, entièrement refondue, avec figures dans le texte. Vol. II. Chimie minérale: métaux. Paris: Hachette. This is one of the best popular works on chemistry ever published, and contains very valuable short biographical notices of savants, chemists, manufacturers, and others, whose labours are quoted or referred to in this book.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2630. J. W. Pollard, Mincing Lane, J. Schofield, Mark Lane, and A. Butel, Bow, Middlesex, "Improvements in the treatment of spent oxides of iron for the purpose of extracting cyanides."—Petition recorded September 4, 1872.

2648. A. C. Duncan and A. Duncan, Manchester, "Improvements in the production of Turkey red."—Petition recorded September 6, 1872.

2845. F. Walton, Staines, Middlesex, "Improvements in oxidising oil, and in machinery to be employed for that purpose."

2847. C. W. Harrison and A. H. Harrison, High Holborn, "Improvements in combining atmospheric air and certain gases for lighting and heating purposes."—Petitions recorded September 26, 1872.

2855. J. McKelvie, Edinburgh, N.B., "Improvements in the manufacture for illuminating gas."—Petition recorded September 27, 1872.

2861. C. W. Siemens, Westminster, "Improvements in the process for the production of iron and steel, and in furnaces or apparatus employed for that purpose."—Petition recorded September 28, 1872.

INVENTION PROTECTED FOR SIX MONTHS BY THE DEPOSIT OF A COMPLETE SPECIFICATION.

2950. T. Greener, Darlington, Durham, and W. Ellis, Gateshead, Durham, "Improvements in the manufacture of iron and in the production of 'fetting' for improving the quality and yield of iron in the process of reduction."—Petition recorded October 7, 1872.

NOTICES TO PROCEED.

1604. R. Ironie, Leith, N.B., and J. Mackintosh, Buenos Ayres, Argentine, "Improvements in the manufacture of paper stock."—Petition recorded May 27, 1872.

1616. J. H. Dennis, Liverpool, "Improvements in the treatment of copper precipitate, and in the utilisation of impurities contained therein."—Petition recorded May 28, 1872.

1649. M. Donbelt, Berners Street, Middlesex, "Improvements in the preparation of iron for purposes where great tensile strength is necessary."—A communication from L. Wloff, St. Petersburg, Russia.—Petition recorded May 31, 1872.

1690. W. Riddell, Bishopsgate Street, London, "Improvements in the manufacture of paper pulp from vegetable fibres, and in apparatus therefor, which apparatus is also designed to be employed in making chloride of lime for bleaching pulp, and in other similar processes."—Petition recorded June 4, 1872.

1739. F. G. Morton, Bermondsey, Surrey, "An improvement in utilising tin-plate scraps or clippings, and in separating the tin and iron contained therein."—Petition recorded June 8, 1872.

1770. J. Birch, Newton Heath, Lancashire, "Improvements in the manufacture of iron and steel, and in apparatus to be used in such manufacture."—Petition recorded June 12, 1872.

1876. S. B. Smith, Birmingham, and J. W. Willans, Middlesbrough, "Improvements in the process of, and apparatus for, smelting iron ores and other ores, and re-heating iron and other metals, parts of which improvements may also be applied to other purposes."—Petition recorded June 21, 1872.

2318. J. Henderson, New York, U.S.A., "Improvements in converting cast-iron into steel and wrought-iron, and purifying cast-iron for foundry and other purposes."—Petition recorded August 3, 1872.

2358. T. Warren, Glasgow, N.B., "Improvements in, and connected with, furnaces employed in the manufacture of glass."—Petition recorded August 8, 1872.

2450. F. Lipscombe, Strand, Middlesex, "Improvements in the treatment of noxious vapours, and in apparatus or appliances in connection therewith."—Petition recorded August 16, 1872.

2518. W. Lochhead, Glasgow, N.B., "Improvements in treating asbestos or amianthus, and applying the same to various useful purposes."—Petition recorded August 24, 1872.

2692. F. A. Gatty, Accrington, Lancashire, "Improvements in producing certain colours on cotton fabrics and yarns."—Petition recorded September 11, 1872.

2766. W. E. Newton, Chancery Lane, Middlesex, "Improvements in the preparation of explosive compounds."—A communication from J. H. Norrbin and J. Ohlsson, Stockholm, Sweden.—Petition recorded September 18, 1872.

2786. P. P. F. Miché, Jubbulpore, East India, "New substances for dyeing, printing, and tanning, and the process employed for treating one of such substances."

2787. P. P. F. Miché, Jubbulpore, East India, "New substances for dyeing, printing, and tanning; also applicable for the manufacture of paper, and threads or yarns."—Petitions recorded September 20, 1872.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of **PRACTICAL CHEMISTRY**, particularly in its application to **MEDICINE, AGRICULTURE, and COMMERCE.**

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake **ANALYSES** of every description.

For Particulars and Prospectuses, apply to **Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.**

North London School of Chemistry, Pharmacy, &c.—Conducted by **Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor** in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The **LABORATORY** will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The **CLASSES** will meet as usual.

The **CHEMICAL and TOXICOLOGICAL CLASS** on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The **LATIN CLASS** on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The **MATERIA MEDICA and BOTANICAL CLASS**, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The **BOTANICAL GARDEN** affords to Students desirous of acquiring a *Practical Knowledge of Botany* every facility for doing so. During the Season **BOTANICAL EXCURSIONS** are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXVI. No. 675.

NOTE ON THE ANALYSIS OF SOAPS.

By F. JEAN.

ALTHOUGH there are still soap-boilers who make *bona fide* soaps, containing no less than 54 per cent of fatty acids, and not more than from 35 to 40 per cent of water, the desire to produce low-priced soaps has led to the introduction of various substances which can only be considered as fraudulent adulterations. Resin (colophonium) is one of the most common of these substances. It is known that resin, when combined with potassa or soda, forms a resinate which, when mixed with water, yields an abundant lather, and this substance is now generally used in the manufacture of soaps. In some countries, however, it is only used in soft soaps. It certainly renders soaps more suitable for use with hard, or even sea, water, but its use is decidedly injurious for some of the applications of soap; for instance, when resin soap is used in the fulling of woollen cloth, it produces peculiar greasy spots, and woollen materials washed with soaps containing resin are difficultly mordanted, and not uniformly dyed. Unfortunately we possess no process by which resin can be accurately separated from the fatty acids. The oldest process of separation—that of Sutherland—consists in boiling the mixture of fatty acids and resin with concentrated nitric acid until the evolution of nitrous acid gas ceases: the resin, thus converted into terebic acid, which is soluble in water, is easily separated from the fatty acids, and these, according to Sutherland, are scarcely acted upon by the nitric acid; but in reality the reaction is not so simple, for, in addition to terebic acid, there is formed azomeric acid, which, being insoluble, remains mixed with the fatty acids, and the latter are, moreover, acted upon to some extent by the nitric acid, the result being that products soluble in water are formed; * the oleic acid is not simply converted into its isomeric elaidic acid, and it is therefore evident that this process does not give reliable results.

Gottlieb's process, as described by Bolley, is altogether useless; the sulphate of magnesium precipitates the bulk of the resinate along with the magnesia soap, and hardly a trace of resin is separated. Rampal's process, described in his memoir on Savonimetry, published as a prize essay by the Société Industrielle de Mulhouse, does not quite answer the purpose. According to this author, the separation of mixed fatty acids and resin is effected by dissolving the same in from 5 to 10 parts of boiling alcohol, and the addition to that liquid of an equal bulk of boiling water; the fatty acids float on the top of this liquid, while the resin is precipitated in the shape of a finely divided powder: it is true that the resin is separated, but in the first place it requires a far larger quantity of water, and some of the fatty acids are precipitated with the resin. If boiling water is added to a boiling alcoholic solution of pure fatty acids, the liquid becomes milky, and remains so for several days: it is thus evident that Rampal's process is not satisfactory.

Caillaet's process admits of qualitatively detecting resin in soap, in the following manner:—10 c.c. of the aqueous solution of the soap to be examined are poured into a narrow test-tube, and dilute sulphuric acid in slight excess is

added; the fatty acids thus separated are then dissolved by the addition of some 2 or 3 c.c. of oil of turpentine, while the resin remains in the liquid as a flocculent substance.

Finding that the processes described in works on analytical chemistry for the separation of resin from fatty acids are not reliable, I considered that a more elaborate examination of the properties of the resinates might lead to the discovery of a more practical process for the separation and estimation of the resin in soap. I first tried to saponify the resin, by boiling it with caustic soda lye; but since the resin floats on the top of the boiling liquid saponification in this way becomes a slow affair: in practice on the large scale the resin becomes mixed with semi-saponified fatty matter, and then the resin itself is readily acted upon. By operating, however, in a small Papinian boiler, at a pressure of 3 atmospheres (75 lbs. to the square inch), the saponification proceeds rapidly. With 100 grms. of resin and 200 c.c. of caustic soda lye, at 15° Baumé = 1.116 sp. gr. = about 8 per cent of dry caustic soda, I obtained complete saponification in half an hour. The saponified material consists of an insoluble portion, A, and of a soluble portion, B; 100 grms. of resin gave 135 grms. of the resinate A and 75 c.c. of the resinate B.

Investigation of the Resinate A.—The resinate A, separated from the soluble resinate B by washing with a caustic soda solution at 5° Baumé, resembles dark-coloured soft soap, of a somewhat gelatinous consistency; its colour is bright brown; the substance is not very soluble in cold water, but it is soluble in boiling water, alcohol, and oil of turpentine. On being analysed I found it contained 54 per cent of yellowish-brown-coloured resin, 3.1 per cent of soda, and 49.2 per cent of water. The aqueous solution of the resinate A, previously freed from excess of alkali, exhibits the following reactions:—the chlorides of sodium and barium, bicarbonate of soda, acetate of lead, sulphate of magnesia, sulphate of soda, chloride of potassium, and ferrocyanide of potassium, form precipitates; caustic soda solution also precipitates the resinate from its aqueous solution; sulphate of potassa, ferricyanide of potassium, neutral borate, and phosphate of soda, fail to give precipitates. Resinate of baryta is soluble in ether. When resinate of soda is decomposed by an acid, there is formed a milky liquid in which flocculent resin floats about; on being boiled these flocks unite, yielding the resin A. This resin, insoluble in water, soluble in alcohol, ether, and oil of turpentine, exhibits an acid reaction. The alcoholic solution forms precipitates with alcoholic solutions of the acetates of lead and copper; it becomes turbid by the addition of water, but the turbidity disappears on the addition of ammonia.

Investigation of the Resinate B.—This substance is soluble in water and alcohol, but insoluble in oil of turpentine and ether; it contains 16.5 per cent of soda. The chlorides of sodium and barium, form precipitates in the aqueous solution of the resinate B; the sulphates of soda and potassa, the ferro- and ferricyanides of potassium, chloride of potassium, and caustic soda, do not produce precipitates, while the precipitation by means of chloride of barium is incomplete, and the precipitate itself insoluble in ether.

The resin B, set free by the action of an acid, is a brittle brown-coloured substance, soluble in alcohol, insoluble in oil of turpentine, and in ether; the alcoholic solution exhibits an acid reaction. The aqueous solution, from which I separated by means of a weak acid the resin B, having been neutralised with soda, yields, after evaporation to dryness, a residue which on being treated with alcohol gave a resinous matter resembling shellac, and exhibiting a slight acid reaction. This body, C, soluble in water, reduces Fehling's liquor, and precipitates nitrate of silver, and sulphate of copper. By the saponification of resin there are consequently three distinct substances generated, viz., a resinate insoluble in alkalies, a soluble resinate, and a substance which is not separated from its acid solutions.

* Boil pure fatty acids for half an hour with concentrated nitric acid, dilute with distilled water, filter, and next saturate the solution with soda, and on evaporating to dryness there will be left an odorous, yellow-coloured mass, which becomes black on being calcined, thus indicating the presence of organic matter soluble in water. Suberic, pimelic, adipic, propionic, butyric, cinnanthylic, succinic acids, and other substances are formed.

The investigation of these resins has led me to adopt the following process for the separation and estimation of resin in soaps:—Dissolve 10 grms. of the soap in 100 c.c. of distilled water; pour into this solution a slight excess of a concentrated solution of pure caustic soda, whereby the soap of the fatty acids and the resinate A are precipitated and separated from the resinate B, soluble in alkaline solution; filter, wash with a solution of caustic soda, and add the washings to the filtrate. The alkaline liquor, which contains the resinate B, is acidified with dilute sulphuric acid, boiled, next poured upon a filter previously weighed and dried at 100° upon which the resin B is left. The acid solution (filtrate from B) is carefully saturated with soda* and next evaporated to dryness; the residue is treated with alcohol to separate the sulphate of soda, and the alcoholic fluid evaporated on a previously weighed porcelain basin, the residue of this evaporation being resinoid matter mixed with glycerine. The presence of this latter body may be ascertained by heating the residue in a test-tube with some peroxide of manganese, a few drops of sulphuric acid, and alcohol of 0·824 sp. gr.; formic ether is then formed, and recognised by its smell, which resembles that of peach-blossom.

I have found that at boiling-heat glycerine decomposes iodic acid, so that iodine is set free. This may be detected by its colouring paper previously impregnated with a solution of starch. This reaction is characteristic for glycerine. After having been washed with a solution of soda, the resinate of soda A and the fatty acids are dissolved in boiling water, and next precipitated by a slight excess of chloride of barium; the insoluble resinate and soap of baryta are separated by filtration, washed and dried at 100°, and next treated with ether, which dissolves the resinate of baryta, leaving the barytic soap in an insoluble state. The ethereal solution is evaporated to dryness and the residue, dissolved in boiling distilled water, decomposed by means of a few drops of sulphuric acid, whereby the resin is set free. This resin is collected on the same filter which already contains the resin B, and having been washed with tepid water is dried at 100° and weighed. The baryta soap suspended in the acidulated water is decomposed by ebullition, and the fatty acids set free are carefully collected and weighed. By this process we ascertain the weight of the resin, fatty acids, and resinoid matter mixed with glycerine and contained in the soap.

It frequently happens that soaps contain large quantities of foreign substances, such as starch (almost always present in soft soap), French chalk, ochre, clay, and the alkaline earthy sulphates, &c., substances fraudulently added for the purpose of rendering soap heavier. These adulterations are readily eliminated by dissolving the soap in alcohol of 0·824 sp. gr., whereby a portion of the chloride of sodium, and the sulphate and carbonate of soda are separated. At the present time the mixing of a concentrated solution of silicate of soda with the still pasty and warm soap mass is very general. I have found a soap of excellent appearance to contain 17 per cent of silicate of soda. As silicate of soda is insoluble in alcohol, it is readily separated by dissolving the silicate in water. The gelatinous silica may be separated either by the addition of a dilute acid, or by boiling with an aqueous solution of chloride of ammonium.

The estimation of the excess of alkali is generally done by treating soap with alcohol, this separates carbonate of soda which is insoluble therein; but since caustic alkali is soluble in alcohol, I estimate the excess thereof in the following manner:—An alcoholic solution is made of the soap under examination; after filtering off the matters insoluble in alcohol, the alcoholic filtrate and washings are placed on a water-bath and a current of carbonic acid passed through the alcoholic solution; all the non-combined alkali is thus carbonated, and becomes insoluble in the alcohol. It is then only required to estimate the quantity of carbonated alkali by volumetry, and to

* If this operation should give rise to the formation of a precipitate, it should be added to that filter which already contains the resin B.

calculate from this result to caustic alkali. By means of this process I have been enabled to correctly determine the quantity of alkali saturated by 100 parts of anhydrous fatty acids.* By saponifying with different quantities of soda pure fatty acids, I have obtained 12·3, 12·5, 12·9, 12·4 of alkali, or on an average 12·9 of soda for 100 anhydrous fatty acids. Soap being really salts, it becomes, when the quantity of combined alkali is known, an easy matter to calculate the thereto corresponding quantity of fatty acids, thus reducing the analysis to a simple alkalimetric operation. From 2 to 3 grms. of the soap to be tested are dissolved in alcohol of 0·824 sp. gr., and, without filtration, this solution is placed on a water-bath and treated with a current of carbonic acid; the liquid is next filtered and the filter washed with alcohol; the filtrate is diluted with water, and then boiled for the purpose of driving off the alcohol; from 5 to 10 c.c. of titrated sulphuric acid are added, and the liquid kept boiling until the fatty acids appear to be quite clear. After cooling and solidification of the fatty acids, the liquid is filtered and the filter washed with tepid distilled water; and next, the excess of sulphuric acid in the liquid is determined by means of a titrated solution of soda. By means of calculation the quantity of sulphuric acid saturated by the alkali of the soap is found. The quantity of combined alkali contained in 100 parts of soap being known, it is only necessary to multiply the quantity of alkali found by 100, and to divide by 12·6 to obtain the weight of the anhydrous fatty acids combined with the quantity of alkali found. The weight of the fatty acids and alkali together being subtracted from 100, gives the quantity of water and impurities contained in the soap which was tested. This process of analysis cannot be applied when soaps contain resin.

In the case of soap made by *empâtage*, it is necessary before treatment with alcohol to boil it first in a solution of common salt, for the purpose of eliminating the organic soda-salts (butyrates, hircates, &c.); for as these salts are not decomposed by carbonic acid, they would behave like alkali combined with fatty acids.

Some soaps often contain a large excess of water. Soaps made with cocoa-nut oil contain frequently a fabulously large quantity of that liquid (100 of the cocoa-nut oil yielding 500 soap). It is therefore of importance to estimate the quantity of water. The usual process, drying of from 2 to 5 grms. of soap previously converted into shavings at 100°, does not give satisfactory results; for while drying, soap swells, and thus retains some water, while a high temperature may cause it to become carbonised. I estimate the water in soap by the following process:—From 1 to 2 grms. of soap-shavings are placed in a previously weighed porcelain capsule and dissolved in the smallest possible quantity of strong alcohol; next I add a weighed quantity of fine dry sand for the purpose of absorbing all the liquid, and then I dry at 110°;† the drying proceeds rapidly, and the sandy powder may be used for the purpose of estimating the non-combined fatty matter by treatment with sulphide of carbon.

A NEW AND READY METHOD OF FORMING PLATINUM-BLACK.

By J. LAWRENCE SMITH.

ALL those who have employed the usual methods of forming platinum-black know that it is attended with

* The theoretical figure as deduced from the formula of the fatty acids would be for tallow, 10·8; for oil, 10·77. According to Rampa¹, the quantity of alkali contained in soaps should be equal to the tenth part of the weight of the fatty acids; according to Roux and Arnauon, it should be 11·5 per cent; and according to Chevreul, taking the average of the three fatty acids, there should be 12·14 parts of alkali (soda) upon 100 parts of anhydrous fatty acids.

† Before weighing, the capsule containing the dried soap should be placed for the purpose of cooling in an exsiccator (over strong sulphuric acid), as soap is hygroscopic, and would again absorb water from the air.

some little trouble: having considerable experience in the decomposing of the platin-chlorides of the alkalis by hydrogen, and by ordinary street gas, the resultant products have been frequently examined, and I find that an excellent platinum-black can be thus prepared; whether equal to the best formed by other processes, I am not prepared to say:—I prefer taking platin-chloride of potassium, and were it not that rubidium and cesium are too expensive, these would be even better, for their atomic weights are higher than that of the potassium, and consequently the particles of platinum are more widely separated. After the platin-chloride is completely reduced, the mass is treated with water to wash out the chlorides of the alkalis thoroughly; the residue is dried at a temperature not exceeding 220° F., when it is ready for use. The operation can be readily conducted in a capsule of porcelain or platinum; the platin-chloride is introduced, and covered with a circular piece of mica a little smaller than the wide diameter of the capsule, with a hole in the centre, through which the tube conducting the gas is introduced. The capsule is then heated by any convenient arrangement by which a temperature not exceeding 400° or 500° F. is obtained, at which temperature it can be maintained with a little management; a small Bunsen burner with a rosette can be used. If the temperature be too high the platinum-black will not be as good as that made at a lower temperature. Washing the platinum-black, after the chloride is taken out, with a solution of caustic potash or soda, and subsequently washing with distilled water, may improve the product.—*American Chemist*.

ELECTRO-MAGNETIC DEPOSITION OF NICKEL.

By J. M. MERRICK, S.B.

IN the following experiments solutions of salts of nickel were subjected to the action of the galvanic current by plunging into the solution a platinum plate, about 3 inches in length by $\frac{1}{4}$ inch in width, connected with one pole of a battery of two medium Grove's cells, while a nickel plate was used in the solution as an anode. In the circuit was placed a sensitive rheostat, by means of which the current could be kept at a definite intensity, and a voltmeter, by which the mixed volume of gases from the decomposed water could be measured. From this volume the volume of hydrogen could be ascertained, and from this volume reduced to dryness, zero, and the normal pressure, the amount of metal which should be deposited in a given time could be found.

The weight of metal actually obtained was found by the increase in weight of the platinum slip used as a cathode, which was provided with a platinum wire soldered to it, by which it could conveniently be attached to the balance.

The difference between these weights, taken into consideration with the character of the deposit, shows the value of the solution used for plating purposes. The time of the action of the battery was generally one hour. The observations were made with a good thermometer and a carefully corrected aneroid barometer.

Acetate of Nickel.—Sp. gr. of solution, 1.0232. The deposit was in large measure pulverulent, velvety, and black, consisting of nickel oxide. This was rubbed off before weighing the cathode, and the result of the experiment showed a deposit of metal equal to one-tenth, 10 per cent of the amount represented by the liberated hydrogen. Smee remarks ("Manual of Electro-Metallurgy," p. 194) that the acetate is a bad solution for obtaining reguline metal.

Cyanide of Nickel and Potassium.—With this solution there was an abundant evolution of gas from the cathode. The deposit was a dull blackish grey, and streaked.

The amount of metal was 14 per cent of the theoretical quantity.

Chloride of Nickel.—This salt was prepared with care

from a nearly anhydrous chloride, and was of a sp. gr. 1.0503.

The deposit was in large measure black, velvety, and easily rubbing off, but leaving a surface of metal underneath. It gave 83.6 per cent of the theoretical amount of nickel.

The velvety oxide was tested for manganese, but none was found. The character of the metallic as a plated surface was poor. It will be remarked that Smee (*loc. cit.*) extols this solution as excellent for plating purposes.

Sulphate of Nickel.—The solution used was made from a very pure and carefully prepared salt, and had a sp. gr. of 1.0223.

The deposit was blackish, and streaked with a greenish deposit above it. This greenish deposit [subsulphate] having been rubbed off, assuming all the rest to be metal, this solution gave a deposit of 52 per cent of the theoretical amount.

Ammonio-Sulphate of Nickel.—This salt was made by adding an excess of ammonia, and then alcohol, to a strong solution of the sulphate of nickel. The precipitated salt was re-dissolved in water.

The deposit was a greyish-brown "mat" (to use a technical word), with some streaks, but no lustre or polish. It was wholly metallic, however, and amounted to 96 per cent of the required amount.

Ammonio-Chloride of Nickel.—A solution of this salt, prepared like the corresponding ammonio-sulphate, gave a bright metallic streak upon the upper side of the cathode, and the rest of the deposit a dull mat, amounting to 96 per cent of the quantity required by theory.

Ammonio-Nitrate of Nickel.—A solution of this salt, of sp. gr. 1.016, gave a deposit largely greenish (subnitrate?), with a various coloured metallic deposit underneath, amounting to 97.4 per cent of the theoretical quantity.

Sulphate of Nickel.—Another (commercial) sample. In this experiment there was an enormous evolution of gas from the cathode, and a considerable evolution from the anode. The other layer of the deposit was greenish. This, on being rubbed off, left a speckled and blotched metallic surface.

The metal gave 107 per cent of the theoretical amount, showing that some oxide must have been weighed as metal.

Nitrate of Nickel.—This was a solution made from a very pure re-crystallised salt. It gave a thick greenish deposit (subnitrate?), with a metallic layer underneath, apparently equalling 130 per cent of the theory, which simply shows how difficult it is by mechanical means to clean the platinum plate from oxide, or other non-reguline matters, in these bad deposits.

Double Sulphate of Nickel and Ammonia.—This gave a good metallic deposit, equal to 93.5 of the theoretical amount.

Double Chloride of Nickel and Ammonia.—This was a solution of the double salt, containing possibly a trifling amount of alcohol. It gave a pulverulent deposit, with a metallic deposit underneath, dirty looking and striped, equal to 47 per cent of the theoretical amount.

Double Sulphate of Nickel and Potash.—This was a solution of a salt prepared with the utmost care, from presumably pure materials, and re-crystallised.

There was a considerable evolution of gas from the cathode, and the deposit was blackish-green in nodules, with a dull metallic layer underneath. This metallic layer amounted only to 37 per cent of the theoretical amount of nickel.

My experiments seem to show that the number of salts of nickel that will furnish a bright metallic deposit of anything near the theoretical amount is extremely limited.

I find it very difficult to reconcile my results with the sweeping statement of Becquerel ("Elements d'Electro-Chemie," 1864, p. 325), viz., that a brilliant white metallic deposit, of a slightly yellowish tint (un dépôt métallique blanc brillant avec une très-légère teinte jaunâtre), can be obtained from a solution of sulphate of nickel in which the excess of acid has been saturated with potassa or soda.

SUGGESTIONS FOR THE EFFECTIVE WORKING OF THE ADULTERATION OF FOOD, DRUGS, &c., ACT, 1872.

THE following is the Report read at a large Meeting of the Association of Medical Officers of Health, held October 28th, 1872:—

1st.—That, in their opinion, the Adulteration of Food Act, 1872, notwithstanding its imperfections, is capable, with proper management, of being made an important and valuable public measure; but to this end it will be necessary to carry out its several provisions in the fullest and fairest manner, having proper regard for the interests of commerce and trade, as well as for those of the public.

2nd.—That if the Act be put in force in this Metropolis, it will be most desirable and expedient that the several analysts appointed by the Vestries and District Boards should work conjointly, and in accordance with some pre-arranged system. This will not only be the means of securing uniformity of results and agreement of opinions, but it will also serve to check the conflict of scientific testimony, and will afford the best guarantee for the full, fair, and effective working of the Act.

3rd.—That to this end, as well as for the sake of economy, it is advisable that all the work of analysis throughout the Metropolis should be performed in as few laboratories as possible, say two; and that skilled assistants should be constantly engaged therein to conduct the analyses, under the superintendence and in the presence of the appointed analysts.

4th.—That as this will entail a large expense, it will be necessary for each of the Food Analysts appointed by the Vestries and District Boards of the Metropolis to contribute, *pro rata*, according to the amount of work done, towards the maintenance of the said laboratories, &c.

5th.—That, guided by the practical experience of two of the members of the Committee, namely, Dr. Letheby, the Professor of Chemistry in the College of the London Hospital, and Dr. Stevenson, the Lecturer on Chemistry at Guy's Hospital, the Committee are of opinion that the work of Analysis, &c., under the Act, cannot be fully and effectually performed at a less charge to the Vestries and District Boards of the Metropolis than from one to two hundred pounds per annum to each of the appointed analysts; for, in considering the question of salary, the Committee have had regard not merely to the great expenses of the laboratory, but also to the time and attention required from each of the analysts, in the supervision and conduct of his laboratory work, and in the proceedings which must arise out of it.

6th.—The Committee are strongly of opinion that if a too strict economy is exercised by the local authorities who are appointed to carry out the provisions of the Act, whether in this metropolis or in the country, the objects of the Act will not be attained, and the interests of the public will not be served; for the Act will either become a dead letter, as in the case of the Act of 1860, or it will be made the medium of persecution, and perhaps also of the most offensive quackery. Already there is evidence of this, and we submit, for the earnest consideration of local authorities, that those who are appointed analysts under the Act should be strictly debarred from giving any certificate or testimonial as to the purity or impurity of any article of food, or drink, or drug, other than for the purposes of the Act, and every certificate should be so worded as to prevent its use for advertising trade purposes.

7th.—That as the success of this Act will largely depend on the manner in which the duties cast on the Inspector are carried out, it is considered advisable that he should be under the direct control of the local authority, or of the analyst, in purchasing or procuring samples of food, drink, or drug, for analytical examination.

HY. LETHEBY, M.B., President.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 1st, 1872.

Rev. WILLIAM GASKELL, M.A., Vice-President, in the Chair.

AMONG the donations announced were a beautiful photographic copy of a fine portrait of the late Mr. John Dawson, of Sedburgh, by Mr. Westall, A.R.A., and a fine photographic portrait of the Rev. Canon Sedgwick, M.A., F.R.S., Honorary Member of the Society, both presented by Canon Sedgwick.

On the motion of Mr. Baxendale, seconded by Mr. Kipping, the thanks of the Society were unanimously voted to the Rev. Canon for his interesting and valuable donations.

"On the Composition of Ammonium Amalgam," by R. ROUTLEDGE, B.Sc.

The substance now known as ammonium amalgam appears to have been first obtained by Seebeck* in the beginning of the year 1808, immediately after Davy had announced his brilliant discovery of the isolation of potassium and sodium by means of the Voltaic battery. Seebeck prepared the amalgam by placing mercury which formed the negative pole of a battery in contact with moistened carbonate of ammonia. About the same time Berzelius and Pontin† obtained the like result with solution of ammonia. This discovery they communicated to Davy early in June, 1808, declaring their conviction that ammonia, like potash and soda, must be an oxide, and that the new substance was a combination of its metallic constituent with mercury. Davy‡ immediately commenced a series of elaborate experiments on the production and properties of the amalgam; and in an account of these experiments laid before the Royal Society in the same month, he first uses the name ammonium to indicate the supposed metallic basis of ammonia. So convinced was Davy that the substance united with mercury in the amalgam was of a metallic nature, and that by combining with oxygen it constituted ammonia, that he was inclined to view nitrogen and hydrogen, if not as oxides of metals, at least as metallic gases.

Davy discovered that the ammonium amalgam was readily produced when an amalgam of potassium was made to act on moistened sal-ammoniac. He found that the electrically prepared amalgam when introduced into a tube rapidly evolved gas, which he describes as consisting of "about two-thirds to three-fourths of ammonia, and the remainder hydrogen." In another experiment, amalgam obtained by potassium was moistened with strong liquid ammonia, and when heated in a tube generated gas which was proved to consist of two-thirds ammonia and one-third hydrogen.

In the following year Gay-Lussac and Thénard|| investigated the ammonium amalgam, and were led to regard it as a triple compound of mercury, ammonia, and hydrogen. They found on putting some of the amalgam prepared by potassium into a tube which was filled up with mercury and then inverted in a vessel of that liquid, that the amalgam gave off, in decomposing, ammonia and hydrogen gases in the proportion of 2½ volumes to 1. But the electrically prepared substance gave off the gases in quite another proportion, the ratio in four different experiments being nearly as 28 volumes of ammonia to 23 of hydrogen. These results were obtained by first drying the amalgam with bibulous paper, then introducing it into a tube containing a little mercury, closing the tube with the finger, agitating it for some minutes with the enclosed

|| "*Recherches Physico-Chimiques*," i., 52.

air, opening the tube after inversion in mercury, measuring the ammonia by absorbing with water, and determining eudiometrically the hydrogen mixed with the residual air. The amalgam was afterwards described by Thénard, in his "Traité de Chimie,"* under the name of "ammoniacal hydride of mercury."

It is interesting to observe that in 1816 Ampère,† in the passage where the now universally received views on the constitution of ammoniacal compounds are first propounded, refers to the amalgam. Speaking of the difficulty of assimilating the constitution of ammoniacal to metallic salts, he remarks—"This difficulty would disappear if we admit that, just as cyanogen, although a compound body, exhibits all the properties of the simple bodies which are capable of acidifying hydrogen, so the combination of one volume of nitrogen and four volumes of hydrogen which is united to mercury in the amalgam discovered by M. Seebeck, and to chlorine in the hydrochlorate of ammonia, behaves in all the compounds which it forms like the simple metallic substances." This theory was more fully developed by Berzelius, and was soon generally received, except as regards the amalgam, concerning which various conflicting opinions were entertained. Daniell,‡ for example, speaks of it as a mere mixture of mercury and gases resulting from the cohesion of the mercury and the adhesion to it of the gases, and he cites the absorption of oxygen by melted silver as a similar case.

Grove,|| in 1841, made a few experiments on the amalgam, and advanced the idea that it is a chemical compound of mercury and nitrogen, merely swelled up with hydrogen.

In 1864, Dr. Wetherill§ performed several ingenious experiments on the amalgam, without, however, attempting any quantitative estimate of its composition. He concludes that it is not an alloy of mercury and ammonium, and that the swelling up of the mass is due to the retention of gas bubbles by virtue of some unexplained action which he somewhat vaguely refers to catalysis.

In the *Annalen der Chemie du Pharmacie* for 1868¶ is a paper by Landolt, in which, after pointing out the discordance of the quantitative results obtained by Davy, and by Gay-Lussac and Thénard, he describes a method by which he attempted a new determination of the relative quantities of ammonia and hydrogen. He prepared the substance from a solution of sal-ammoniac, separated from the mercury, which formed the negative pole, by a porous cell. The amalgam, when removed from the circuit, was washed in a stream of water to get rid of the adhering solution of sal-ammoniac, which always contains free ammonia. It was then immediately plunged into dilute hydrochloric acid of known strength, and the hydrogen evolved was received into a graduated cylinder placed over it, while the ammonia was estimated by determining the amount of unneutralised acid in the liquid. Two experiments gave results corresponding respectively to 2.15 and 2.4 volumes of ammonia to 1 of hydrogen. These figures of Landolt's cannot be considered satisfactory, neither nearly agreeing with each other, nor approximating to the ratio 2:1 sufficiently closely to justify his conclusion that they "completely confirm the results formerly obtained by Davy." Indeed Landolt points out a serious defect in his process, namely, that however rapidly the amalgam may, after washing, be transferred into the acid, the adhering water will nevertheless take up some more ammonia from the continuously decomposing substance while the hydrogen escapes.

It must be observed that Davy himself appears to have found a difficulty in obtaining consistent results, for he does not seem to have ever entirely satisfied himself as to the proportions of the two gases. These are the words in which he sums up his observations:—"As it does not seem

possible to obtain an amalgam in an uniform state, as to adhering moisture, it is not easy to say what would be the exact ratio between the hydrogen and ammonia produced, if no more water was present, than would be decomposed in oxidating the basis. But in the most refined experiments which I have been enabled to make, this ratio is that of one to two; and in no instance in which proper precautions are taken is it less, but under common circumstances often more. If this result is taken as accurate . . . , &c."

This statement of Davy's being apparently the only authority for the assertion that the decomposing amalgam gives off the gases in atomic proportions, and yet being in conflict with Gay-Lussac and Thénard's results, it appeared to me desirable to attempt to obtain more exact determinations.

I used amalgam prepared by electricity in the manner described by Landolt.

A simple mode of eliminating the disturbing effect produced by the attraction of ammonia for moisture suggested

itself. A U-shaped glass tube was provided, open at both ends, about 1.4 centimetres in diameter, and having its shorter limb 40 centimetres long. At the bottom of the longer limb, just above the bend, there was an outlet tube to which was attached a piece of caoutchouc tubing closed by a pinch-cock. Mercury was poured into the tube until it filled about two-thirds of the shorter limb, into which was then introduced the amalgam after the latter had been wiped with filtering-paper. Then into the end of the limb containing the amalgam, a caoutchouc stopper, perforated with a small opening, was immediately thrust so far that its upper surface came a little below the rim of the tube. The decomposition of the amalgam was then allowed to proceed for a few minutes, during which period any moisture adhering to the amalgam or present in the tube would become completely saturated with ammonia, and then the two gases would begin to escape through the perforation in the stopper in the proportions in which they are really evolved. Mercury was now poured into the open end of the longer limb until the amalgam just made its appearance at the top of the hole in the stopper, which was then closed by pushing in a piece of glass rod. The evolved gases being now retained in the tube pressed up the mercury in the longer limb, and it was from time to time drawn off by the outlet tube to prevent undue pressure on the stopper. When the decomposition was complete, which usually occurred in about 1½ hours (but in one case more than 2½ hours were required), the mercury was brought to the same level in both limbs and the space occupied by the gases was marked on the tube. A little mercury was then let out so as to make the pressure on the gas somewhat less than that of the atmosphere, and the space above the stopper was filled with hydrochloric acid diluted with a little water. The glass rod was then carefully withdrawn for an instant so that a few drops of the acid might enter the tube. The ammonia gas present was of course immediately absorbed, and the mercury having been again brought to the same level in both limbs, the space occupied by the residual hydrogen was marked on the tube. The volumes occupied by the gases were determined by finding the quantity of water required to fill them from a burette.

The following are the results of four experiments:—

No. of Experiment.	Volume of the Mixed Gases.	Volume of Residual Hydrogen.	Volume of Ammonia Absorbed.	Volumes of Ammonia found for one Volume of Hydrogen.
	c.c.	c.c.		
1	20.8	7.0	13.8	1.97
2	18.2	6.2	12.0	1.93
3	12.8	4.3	8.5	1.98
4	13.6	4.6	9.0	1.95

I believe these figures are as nearly accordant with the atomic proportions as could be expected from the means employed, where the possible error in determining the volumes might amount to perhaps 0.2 c.c.

In another similarly conducted experiment, in which it was sought to obtain as much gas as possible, the tube was closed too soon, and the result showed a deficiency of ammonia, but is otherwise interesting:—

Experiment 5.			
Volume of Mercury in the Amalgam.	Volume of Amalgam.	Volume of the Mixed Gases.	Volume of residual Hydrogen.
11.8	30.5	49.0	18.0

A new observation on the amalgam has recently been made in America by Professor C. A. Seeley,* who found, by subjecting it to varying pressure that its volume changes, apparently in accordance with Mariotte's law. He employed simply a glass tube fitted with a plunger, and did not measure the pressures or volumes. His conclusions were that the amalgam is a mechanical or physical mixture of liquid mercury with the gases ammonia and hydrogen, and that its semi-fluid consistence is due to the mixture having the nature of a froth.

Being desirous of submitting Seeley's remark on the compressibility of the amalgam to the test of direct measurement, I subjected the electrically formed amalgam to pressure in a glass tube 48 centimetres long, and 1.3 centimetres diameter. The pressure was applied by connecting the tube with a syringe, by which air could be forced into the apparatus, and the amount of the pressure was measured by a column of mercury in an open manometer. There was some difficulty in measuring the volume owing to the occasional escape of bubbles of gas, which caused abrupt alterations of the level. The results obtained are given in the following table, which also contains a column of volumes calculated on the supposition that the amalgam is a mere mixture of fluid mercury and gas, allowance being made for the pressure on the gas due to the column of mercury in the amalgam itself. The extreme case was assumed, namely, that this additional pressure is represented by a column of mercury half the height of the amalgam.

* CHEMICAL NEWS, June 10, 1870

Five points deduced from the mean results of experiments 15 to 24 having been laid down in relation to rectangular axes, the curve (1) which passed through them is represented in the diagram, which shows also the curve (2) through five points representing the calculated volumes, and a line (3) representing volumes corresponding to the

pressures which were applied to the top of the columns of amalgam.

The diagram and figures sufficiently show that the compressibility of the amalgam agrees nearly with the supposition of its being a mixture of gas and mercury, but that it is, however, somewhat less compressible. This, no doubt, is owing chiefly if not entirely to its want of fluidity.

I think that from these experiments I am warranted in drawing the two following conclusions, viz.:—

(1). In the fact of the gases being evolved in atomic proportions, we have the clearest proof that the ammonia and hydrogen are chemically combined.

(2). The compressibility of the mass proves that the enlarged volume or swelling up is due mainly, if not entirely, to free gases entangled in it.

In connection with the first of these conclusions arises the further question whether the NH_4 is combined with the mercury. That it is so combined appears in the highest degree probable from the apparently uniform diffusion of the NH_4 throughout the mass, and from the fact that such a union would be only one additional instance of the innumerable cases in which this radical plays the part of a metal. Seeley says, that if the radical NH_4 be contained in the amalgam at all, it must be in the state of gas. But the figures furnished by my fifth experiment show that if this supposed NH_4 gas had the normal molecular volume, and existed in the amalgam from the beginning, a force of two atmospheres would be required to compress it within the amalgam. The decomposition therefore is progressive, and points to the existence of a real compound of NH_4 with the mercury. We may therefore admit, that such a compound is originally formed, and decomposes rapidly into mercury, ammonia, and hydrogen, while the gases becoming entangled in the mass impart to it that remarkable turgescence, which is not, however, a property of the original compound (or ammonium amalgam), but merely an accidental result of its decomposition.

As to the cause of the retention of the gases, I am not prepared to offer an opinion, further than that its explanation would probably involve physical rather than chemical considerations.

I have to express my obligation to the kindness of Dr. Roscoe for the use of the appliances of the laboratory at Owens College, where the experiments were carried out, and I am also indebted to him for valuable suggestions.

Sir Humphry Davy, Bart.—A colossal statue, which has cost £600, has been erected to the memory of Sir Humphry Davy at Penzance, his native place. The statue is placed in front of the Post-Office, near to the birth-place of the great philosopher.

NOTICES OF BOOKS.

Statements relating to the Home and Foreign Trade of the Dominion of Canada; also Annual Report of the Commerce of Montreal for 1871. By WM. J. PATTERSON, Secretary to the Board of Trade. Montreal: "The Gazette" Printing House. 1872.

Mineral Resources North of Port Augusta. Ordered by the House of Assembly to be printed and lithographed, April 17th, 1872.

Mineral Statistics of Victoria for the Year 1871. Presented to both Houses of Parliament by His Excellency's Command. Melbourne: John Ferres.

ALTHOUGH the first two reports do not include subjects that we can discuss, we must bear witness to the extreme care and accuracy with which the matter has been collated. In the third report, however, there is much that will interest our readers, especially in the laboratory report by Mr. J. Cosino Newberry, B.Sc., Analyst to the Mines Commission, under whose direction over one hundred analyses, examinations, and assays have been made during the past year. The mining assays have only a local interest, and we omit them—unwillingly, because of the care which they evince; but the analyses of rocks and minerals are too instructive to be so summarily disposed of. An analysis of halotrichite, from near Mudgee, N.S.W., crystallised in needles, and massive, colour white, shows the composition to be—

Alumina	11.67
Magnesia	4.41
Sulphuric acid	39.88
Cobalt	traces
Iron	"
Soda	"
Water	42.24
Silica	0.20
	98.40

A dense, flint-like rock, of yellow colour, occurring in granite, gave—

Silica	98.10
Alumina	1.77
	99.87

Fibrolite, from Gippsland, gave—

Silica	36.90
Alumina	60.73
Lime	0.63
Magnesia	0.33
Water	1.50
	100.09

Infusorial earth, from near Talbot, occurring in quantities, and of considerable value, gave—

Silica	83.88
Alumina	7.41
Lime	1.24
Magnesia	0.75
Water	6.23
	99.51

Fire-clay, bricks of which stand a high temperature without softening or cracking, the most extreme heat of an assay furnace being insufficient to round the thin edges, gave—

Silica	67.2
Alumina	29.0
Water	4.0
	100.2

Analyses were made with the view of ascertaining the nature of the so-called lava-streaks found cutting the silurian shales and sandstones in various rocks, and the results prove that they are more or less decomposed dyke-stones, probably basaltic. Of a rock, 51.78 per cent of which was soluble in hydrochloric acid, the soluble portion gave—

Water	13.81
Silica	8.81
Alumina	18.01
Peroxide of iron	8.80
Lime	2.34
Magnesia	trace
Potash	0.90
Soda	trace
Phosphoric acid	0.40
Soluble sulphates and chlorides	trace

53.07

The excess in the analysis is probably due to the oxides of iron being determined as peroxides. They occur as protoxide, peroxide, and magnetic oxide. The insoluble 48.22 per cent consisted of—

Silica	33.75
Alumina	13.77
Lime	0.70

48.22

Some experiments were made with the view of finding means of clearing the muddy waters of reservoirs. The purest waters are, as a rule, those in which mud and organic matter remain longest in suspension. Water from the Expedition Pass Reservoir stood in a bottle in the laboratory for more than six months without depositing the clay held in suspension. The soluble matter was chiefly chloride and carbonate of sodium, and was present in only small quantity. Another water stood for three months with like results. Both waters contained more clayey than organic matter, and were rendered clear by an addition of chloride of calcium. One part of this salt in 1000 of water cleared it in less than one hour; 1 part in 2500 of water, in five hours; 1 part in 5000, in six hours; 1 part in 10,000, in twenty-four hours. When, however, the water contained more organic matter than inorganic or clayey matter in suspension, the calcium salt did not act so readily, but was aided by an addition of lime: as little as two grains of quick-lime cleared a gallon of water in twelve hours. Three or four grains of alum or chloride of aluminum answered the same purpose; but there are many objections to the use of alumina salts.

We have selected but few of the tabulated results, the entire arrangement of which may be fully commended to the reader.

El Agua del Rio de la Plata su Analisis Quimico con Observaciones sobre las Variaciones en su Composicion; in forme presentado a la Comision de Aguas Corrientes de la Ciudad de Buenos-Ayres. Por JUAN J. J. KYLE, Catedrático de Quimico en el Collegio Nacional. Buenos-Ayres. 1872.

THIS small pamphlet contains valuable information as to the chemical composition of the waters of the rivers Rio de la Plata, Rio Parana de las Palmas, and that of the water supplied to the city of Buenos-Ayres. The author has analysed the water of the above rivers at various depths and in various states of the tide. The result of this analysis he gives in two tabulated forms, from which it appears that the water tested was of medium purity, as also was that supplied to Buenos Ayres.

The method of analysis used was that recommended by Messrs. Wanklyn and Chapman.

CORRESPONDENCE.

VANADIUM IN TRAP-ROCKS.

To the Editor of the Chemical News.

SIR,—I trust you will allow me a little space in your paper for some observations on the prospective importance of such researches as those of Mr. Apjohn, published in your last issue. The earlier chemical history of rock masses was confined to empirical analysis, including only the most common elements. Two important steps have been taken in advance—one by Professor Haughton, the other by Bunsen. The former showed, by the discussion of his analyses of felstones, that these may be regarded as mixtures of orthoclase and quartz. Bunsen deduced a theory, from his examination of the igneous rocks of Iceland, that all such rocks may be referred to two types, some belonging to one type, some to the other, and the remainder being mixtures of the two in various proportions, the proportions being determinable by analysis. There are trap-rocks in the Isle of Man which cannot be brought within the scope of Bunsen's formulæ; but this proves nothing against the *idea* involved—it only shows that Bunsen's experiments did not cover ground enough to enable the formulæ of the two fundamental types to be determined. The third great step which, as it seems to me, remains to be taken, is that foreshadowed by the work of those who, like Mr. Apjohn, seek for the rarer elements in common stones.

Geologists divide all rocks into two classes, the igneous and the aqueous. The aqueous rocks, being derived from the igneous, must, viewed generally, have the same ultimate chemical composition, *minus* what has been washed out by water. The difference between the two kinds of rocks accumulates in the sea in the form of salts held in solution. Some of these salts must have gone on accumulating in the sea since water first began to condense upon the solidifying poles of the once fluid earth; other of the salts have continually been segregated out by organisms, to form the carboniferous strata. As the igneous rocks which protrude through the older strata rarely contain carbonic acid, it seems reasonable to suppose that nearly all the carbonic acid contained in the sea-deposited carboniferous rocks was once atmospheric. If so, the pressure of the atmosphere must, in early geological eras, have been enormously greater than it now is, and consequently the early sea have been once at far above the temperature at which water now boils. The powerful chemical action of water heated under pressure in an atmosphere of carbonic acid has been often insisted upon as a means of accounting for the large proportion of salts contained in some mineral waters. The decomposition of the alkali and alkali-earth silicates of the primordial earth-surface must therefore have proceeded at a far more rapid rate in early ages than in later times. Meanwhile the more soluble constituents were constantly being dissolved out of the rocks, in part to go on accumulating in sea-water to this day, and in part to furnish the cases or skeletons of organisms, which to this day are being deposited to form ocean bottoms. Speaking generally, the insoluble residue ultimately left of the igneous rocks, after repeated denudation, re-melting, degradation, and re-deposition, would be mainly a silicate of alumina or clay. It is common with geologists to speak of all these rocks as if their ultimate composition were the same; but the well-known difference in fusibility between the aqueous and the igneous rocks is alone sufficient to show that the composition is different, and different in the direction that might have been predicted.

If the proportion of, say lime, in the oldest igneous and the newest sedimentary rocks were known, the difference would be represented by the lime present in those carboniferous strata that have been formed by organisms out of the sea, taken together with the comparatively insignificant portion remaining in solution. If the total quantity of lime so segregated were known, the mass of original igneous rock acted upon might be calculated. Such data cannot be obtained; but if we take, say vanadium, and ascertain, by sufficiently numerous experiments, an approximation to the proportion of it contained in the oldest igneous rocks, and prove either its absence, or determine its proportion, in the later sedimentary rocks, then we may look in the existing sea for the whole of the difference. Now it is very easy to detect vanadium in sea-water, and it could not be very difficult to determine the proportion in which it is present. This once known, the total quantity contained in the ocean could be roughly calculated, and hence the total thickness of original earth-crust that had been acted upon by the sea. Such a calculation could be verified or controlled by the discussion of the data afforded by corresponding experiments, as to the proportions present in the two kinds of rock and in sea-water, of other elements, as iodine or osmium.

I have assumed in this argument that the earth's crust was originally homogeneous, of the same chemical composition throughout, with the rarer elements equally diffused. This assumption is not, however, essential for the end in view, provided an average composition can be established for the older igneous rocks. Many of the trap-rocks are doubtless only sedimentary rocks re-melted. Most are probably a mixture of re-melted aqueous rocks, with original earth-crust. Other things being equal, those igneous rocks which protrude in great mountains through the older sedimentary strata, and which possess a great equality of composition all round, would be most likely to represent the original earth-crust. Such a mountain is that of Penmaenmawr, in North Wales. The rock known as Rowley Rag, near Birmingham, closely resembles it in chemical character. By a comparison of a sufficient number of specimens of such rocks from different localities, with respect to the proportion—say of vanadium—contained in them, it would become known how far such proportion might be trusted as an indication of the original constitution of the rock. Further examination of specimens from trap-dykes traversing more recently deposited rocks would show if the proportion of the vanadium was less in such; and ultimately the true proportion contained in the original crust would be inferred, together with a means of judging of the origin of traps and basalts. If such a result were not obtained, even, it would be worth while to know that the contrary proposition was true,—that the composition of the earth's crust was not originally homogeneous; and one or the other conclusion must result from sufficient investigation, conducted as here suggested.

But the assumption of the original homogeneity of the earth's crust is not without facts in its support. The search after the rarer elements has not been diligent enough, nor are the methods of detecting them, when present in small proportion, effective enough, to justify any conclusion as to their total absence from ordinary rocks. Some of the elements most sought after, and others the means of detecting which are extremely delicate, are known to be almost universally diffused. Gold, silver, copper, and iodine, come into this category. Platinum appears to have been found whenever sought for in the larger masses of igneous rocks. The mountains of Auvergne, in France, are known to contain it throughout. It is present in the Penmaenmawr rock, and in all the clays I have ever examined for it, which are many. The close general chemical resemblance between great masses of igneous rocks, all the world over, is well recognised. What is now needed is, to trace the rarer elements through all these, and to follow up their disappearance—for such of them as do disappear—into the later sedi-

mentary rocks. Then the elements missing in the latter should be found in sea-water.

The great diversity of minerals, the accumulation of rare elements in special localities, and the various dominant mineral characteristics of different countries, furnish no valid argument against the position here taken. For what forces have been at work! and for how long? The most complex and rare of minerals are found just where they might be expected to be found—in high latitudes. For then great geological changes must first have begun, and gone on under the influence of water, while as yet no crust was formed in equatorial regions, since astronomers tell us that the axis of the earth has not changed its position from the earliest times, except within the swing of the precession of the equinoxes. It seems as if all accumulations of special minerals had taken place very gradually, and under influences which, however obscure, are not utterly unintelligible. Mineral veins are usually found in the neighbourhood of faults, which, by causing the formation of cavities, determine the drainage from, it may be, miles of superincumbent rock, and from a surface hundreds of miles in extent. When we consider that from any ordinary piece of slate (and still more of a trap-rock) traces of metals, precipitable from acid solution by sulphuretted hydrogen, may always be obtained, it is not wonderful that the drainage from probably hundreds of cubic miles of rock, all converging to one axis, should fill up cavities with deposits of minerals in abundance, the elements of which can only with difficulty be detected in the parent rock. Then either denudation of miles of superincumbent rock, or upheaval, or alternations of both, proceeding through geological eras, make such deposits accessible, and at the same time make the origin obscure. Vanadium appears to be an element the estimation of which in rocks is well adapted for the purpose of distinguishing between the two great classes of rock, with their varieties. It must be an element that water extracts with some ease, or the sea could not contain so much as that a tumbler full of sea-water should suffice for its detection, while it is classed among the rarest of terrestrial elements.—I am, &c.,

Ramsay, Isle of Man,
October 21, 1872.

E. SONSTADT.

PS.—I have referred to the detection of vanadium in sea-water; and, although it is well known that vanadium must be there, since it is found in crystals from the mother-liquors of the soda manufacture, yet it may be expected that I should state the method I have followed of directly detecting it. If to a specimen of sea-water about a fourth of its volume of a saturated solution of pure iodate of potassium is added, after a few hours a precipitate forms, consisting essentially of iodate of calcium, but containing vanadium, and giving the usual blowpipe reactions of vanadium. I have used other methods, but this is the best.

A great number of salts, more or less soluble in pure water, are totally insoluble in a strong solution of iodate of potassium. Didymium, for instance, is so completely precipitated by this reagent, that the filtrate gives, through a thickness of several inches, no trace of absorption lines in the spectroscope. The alkalies, magnesia, alumina, and glucina, are not precipitated. Stas had difficulty in procuring iodate of potassium that remained colourless on exposure to the air. But if a solution of iodate of potassium is concentrated sufficiently to crystallise slightly, every trace of impurity capable of causing colouration of the crystals goes down with the first crop; and subsequent crops of crystals are snowy-white and permanent in the air, and do not give a coloured bead before the blowpipe. The precipitate which iodate of potassium gives with sea-water appears to contain osmium as well as vanadium, and even in larger proportion. If alcohol is added to the sea-water a few hours before the addition of the iodate, the precipitate is free from both vanadium and osmium.—E. S.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 21, 1872.

In addition to a large number of original memoirs and papers relating to mathematics, physics, geography, meteorology, applied and pure mechanics, and astronomy, this number contains the following original paper relating to chemistry:—

Action of Crystallised Sugar upon the Cupro-Potassic Reagent of Barreswill.—E. Feltz.—After first observing that the estimation of glucose is based upon the reduction of the cupro-potassic liquor heated to ebullition, the author states that it has been inferred that refined and crystallised sugar exerts no action upon the reagent alluded to, and describes at length a series of experiments from which it appears that pure and best refined sugar also gives the well-known reaction—viz., separation of sub- or red oxide of copper, especially in the presence of an excess of alkali. While the author remarks that Dr. Scheibler pointed out in 1869 that the estimation of glucose is vitiated in a mixture of the two sugars under certain conditions, he forgets that many years ago the late Dr. G. J. Mulder, in an essay on sugar, proved that the cupro-potassic test fails unless it is carefully prepared, and that no higher temperature than about 80° or 90° should be applied; as above that temperature even the cupro-potassic liquor alone is liable to reduction (see *Jahresbericht über die Fortschritte der Chemie*, von J. v. Liebig und H. Koppe, für 1850, pp. 614, 675, 676).

La Revue Scientifique de la France et de l'Etranger, October 26, 1872.

This number contains no original papers relating to chemistry, but we call attention to the following memoirs:—

Geology of the Secondary and Tertiary Basins of the Sub-Cevennic Region (Région sous Cévennique).—Dr. Bleicher.—Illustrated with woodcuts and diagrams.

Glycogenesis in the Invertebrate Animals, and General Character of Nutrition and Glycogenesis.—Dr. C. Bernard.—The continuation of a series of lectures on general physiology.

Neues Jahrbuch für Pharmacie und Verwandte Fächer, von Dr. F. Vorwerk, January, 1872.

This number (which has been delayed in transmission) contains the following original papers relating to chemistry:—

Analysis of Potable Waters by means of a Titrated Soap-Solution.—Dr. Graeger.—The detailed account of a peculiar volumetric method of water analysis by means of an alcoholic soap-solution of known strength. It appears from the results of this method, as compared with the gravimetric method, that for practical purposes this plan of analysis is sufficiently correct to estimate the carbonate of lime, lime, magnesia, sulphuric acid, chlorine, and carbonic acid in drinking water.

Formation of Corrosive Sublimate in Powders Containing Calomel.—G. Vulpius.—The author has instituted a series of experiments to ascertain the correctness of the assertion that calomel when mixed with other powders becomes converted into corrosive sublimate; the results of these researches may be summarised as follows:—No corrosive sublimate is formed within twenty-four hours when calomel is mixed with saccharum album, saccharum lactis, magnesia usta, magnesia hydrico-carbonica, and natrium bicarbonicum. After three months no corrosive sublimate is formed in mixtures of calomel with magnesia usta, magnesia hydrico-carbonica, and any kind of refined sugar or milk-sugar, but faint traces are formed in mixtures containing calomel, natrium bicarbonicum, and refined lump-sugar. By treatment with water, corrosive sublimate is only formed in such mixtures of calomel as contain magnesia usta and bicarbonate of soda. Rather large quantities of sublimate are formed in powders composed of calomel, sugar, and bicarbonate of soda, if the mixture becomes damp and is kept for a long time. No sublimate is formed when a powder consisting of calomel and bicarbonate of soda is digested with water acidulated with hydrochloric acid. Pepsin does not favour the formation of corrosive sublimate.

Hager's Method for the Quantitative Estimation of the Cinchona Alkaloids by means of Picric Acid.—O. Medin.—This essay treats at great length on the quantitative estimation of the cinchona alkaloids by precipitation with a solution of picric acid; the quantity of alkaloids present in cinchona barks may thus be readily and accurately ascertained.

February, 1872.

This number contains no original papers relating to chemistry.

March, 1872.

Some Double Salts of Protoxide of Iron, and their Applicability for Titrating the Solution of Permanganate of Potassa.—Dr. Graeger.—This essay contains the detailed account of the behaviour of the following double salts of iron with permanganate of potassa solution of a known strength:—Sulphate of protoxide of iron and ammonia, potassa, soda, magnesia, and oxide of zinc.

Some Reactions of Quinine and Morphine.—F. A. Flückiger.—The results of the author's researches may be summarised as follows:—The thalleiochin reaction is limited to from 1-4000th to 1-5000th; Vogel's reaction with ferrocyanide of potassium is not so sensitive. Very dilute solutions of quinine are best detected by the bromine reaction, which indicates even 1-20,000th of the alkaloid; by means of chlorine-water and ammonia, 1-1000th part of morphine may be detected, while the iodic acid reaction is ten times more sensitive. Bromine and ammonia are useless for the detection of morphine; in a mixture of salts of quinine and morphine, the test for either of these bases may be called forth at will by means of chlorine and ammonia.

April, 1872.

Preparation of Pure Hydrochloric Acid.—Th. Diez.—The crude hydrochloric acid of commerce is first diluted, by the addition of water, to a sp. gr. of from 1.14 to 1.13, and it is next treated with sulphuretted hydrogen gas until it smells strongly of the gas. The liquid is next filtered, and then poured into a tabulated retort and heated until the sulphuretted hydrogen is eliminated. The test of solution of corrosive sublimate having been applied, the bulk of the acid is distilled over at a gentle heat, a few fluid ounces only being left in the retort, so that any chloride of iron left in the acid may be retained.

Quantity of Starch contained in Different Varieties of Potatoes.—Dr. Raab.—The tabulated form containing the record of experiments with sixty-one different varieties of potatoes, in which the author has estimated the total percentage of dry substance and the total quantity of starch. It appears from this research that the percentages alluded to vary, for dry matter, from 15.64 to 34.25, and the percentage of starch from 8.79 to 26.09.

Mejillones Guano.—H. Vohl.—This material occurs native and in large quantity near the Bay of Mejillones (Bolivia). In 100 parts, this substance consists of:—Lime, 30.6636; magnesia, 7.9193; peroxide of iron, 0.1466; alumina, 0.0047; potassa, 0.5051; soda, 1.4532; phosphoric acid, 35.86803; chlorine, 2.2250; sulphuric acid, 1.6036; silica, 0.0459; carbonic acid, 1.5926; water driven off at 100°, 7.6858; non-nitrogenous organic matter, 6.5189; nitrogen, 0.7675; granules of granite insoluble in HCl, 2.2830; loss, 0.7249. The author states that this guano occurs in pulverulent sandy state, and that it is readily acted upon by carbonic acid and water, and thus rendered available for plants, while, in consequence of its high percentage of phosphoric acid, it may be used with advantage for the preparation of phosphate of ammonia and other phosphatic preparations.

May and June (double number), 1872.

This number contains no original matter relating to chemistry.

The American Journal of Science and Arts, October, 1872.

This number only contains one original paper relating to chemistry:—

Results of a Chemical Investigation of some Points in the Manufacture of Malleable Iron.—Russell W. Davenport.—Reserved for full reproduction.

This number contains several important papers relating to natural history, geology, astronomy, and physiology.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, June, 1872.

On Hypophosphites.—C. Rammelsberg.—This monograph has been already alluded to (see *CHEMICAL NEWS*, vol. xxvi., p. 23).

Behaviour of the Diamond and of Graphite when Strongly Heated.—G. Rose.—This essay, illustrated by several engravings, is divided into the following sections:—Ignition of diamond without access of air; ignition of diamond with access of air; on the peculiar and regular impressions which are formed on the diamond during its combustion; on the so-called carbonado (a peculiar variety of diamond found in Bahia); behaviour of graphite when ignited.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, June 27, 1872.

We receive this periodical very irregularly, this number having only just arrived.

Preparation of Sugar Colour from Glucose.—M. Krothe.—The detailed description of the industrial method of converting glucose into caramel, simply carried on by heating the glucose, which is largely made abroad by the action of sulphuric acid upon starch in boiling-water, with the addition of a small quantity of carbonate of ammonia,

the materials being well stirred and carbonisation prevented. This kind of caramel is largely used to give a fictitious strength to beer.

Industrial Preparation of Hydrogen.—M. Giffard.—By first reducing to the metallic state a peculiar kind of iron ore found at Chateauroux (France) by means of oxide of carbon, finely-divided iron is obtained, which is used to prepare hydrogen, which thus costs only 4d. per cubic metre (35.31 English cubic feet) and may be used for various heating, illuminating, and air-balloon filling purposes.

Applications of Sulphurous Acid Gas.—M. Chaudet.—The author proposes to apply sulphurous acid gas—obtained in the usual way from pyrites or burning sulphur—for the purposes of saturating urine, the contents of *fosses d'aisance*, ammoniacal gas-water, the waste soap-water from woollen and other industries, partly for disinfection, but more particularly for obtaining valuable products by evaporation; the sulphurous acid gas is forced into the liquids by means of blowing-vans or force-pumps.

Note on the Determination of the True Zero of Thermometers.—Ch. Tellier.—Reserved for full translation.

American Journal of Pharmacy, October, 1872.

This number contains the following original papers relating to chemistry:—

Soluble Sulphate of Quinine.—J. Donde.—150 grms. of the ordinary sulphate of quinine are taken, and gradually put into a mixture of 22 grms. of concentrated sulphuric acid and 2 litres of water; this mixture is occasionally agitated until solution has taken place, and, after filtering, the fluid is concentrated by evaporation until the liquor is reduced to 600 grms.; the crystals are taken out twenty-four hours afterwards, and the remaining mother-liquor is again evaporated in order to obtain more crystals.

Preparation of the Bromides of Quinine, Morphine, Strychnine, and Calcium.—G. Macdonald.—The bromides of the alkaloids may be readily prepared on the small scale by precipitating the solutions of their neutral sulphates with bromide of barium, the latter to be prepared by saturating hydrobromic acid with carbonate of baryta; the bromide is very soluble, and it is not necessary to crystallise the solution. The bromides of the above-named alkaloids may be prepared for pharmaceutical purposes by a similar method. As regards bromide of calcium, the author directs to prepare it by double decomposition, aided by boiling a solution of bromide of ammonium, to which milk of lime (the lime to be made from pure white marble) is added, until ammoniacal vapours cease to be evolved; the salt is very deliquescent and requires to be kept in well-stoppered bottles.

Occurrence of Amygdalin, and Generation of Hydrocyanic Acid.—S. Henschen.—The author instituted a number of experiments by which he proved the presence of hydrocyanic acid by means of paper dipped in tincture of guaiacum and a solution of sulphate of copper, carefully avoiding ammoniacal vapours. Amygdalin treated with the meal of peas and of rye yielded hydrocyanic acid, but none with sifted wheat-flour. Sweet almonds were found to contain a minute quantity of amygdalin. The seeds of apples, pears, quinces, *Sorbus aucuparia*, *Sorbus latifolia*, all yielded HCN; traces of that acid were obtained from vetches. The generation of HCN from vegetables is generally regarded as conclusive evidence of the presence therein of amygdalin, but Dr. Peckolt ("Analyses de Materia Medica Brasiliensia," Rio Janeiro, 1868) was unable in fifteen cases to prepare amygdalin from the root of the *Manihot utilisima* (the arrow-root plant) which copiously generates hydrocyanic acid with water. Vetches yield, instead of amygdalin, a new crystallisable body, $C_8H_{11}N_3O_8$. It would appear from some of the author's experiments that amygdalin may occur in plants without the simultaneous presence of emulsin; to ascertain the presence of amygdalin, the vegetable material is finely powdered, the acid which may be present is neutralised by chalk, some coarse rye-meal or a similar ferment is added, and then some water, after which the fermentation is allowed to proceed, and the presence or absence of HCN established as mentioned above.

Manufacture of Olive Oil in California.—Dr. J. M. Maisch.—It appears from the contents of this essay that the cultivation of the olive tree is very successful, and that the preparation of olive oil is becoming a leading industry in California.

Cotton-Seed Oil.—Dr. J. M. Maisch.—The preparation of this oil is carried on to a very large extent in some parts of the United States, 150,000 tons of seed being used annually; the oil-cake is largely exported to England, and the oil goes mostly to Bordeaux, Barcelona, and other olive-growing parts of Europe, from whence, after refining, it comes back as pure olive oil; a large proportion of raw cotton-seed oil is refined in London, and thence exported.

Les Mondes, October 24, 1872.

Obituary.—We learn with regret the demise of the celebrated physicist Jacques Babinet, who died on October 21, aged seventy-eight, having been born at Lusignan on March 5, 1794. The deceased *savant* was well and deservedly known as an excellent mathematician and physicist.

Deposits of Phosphatic Minerals at the Locality Known as the Perte du Rhone.—L. Grasser.—In a letter addressed to MM. Lomer and Ellershausen, at Geneva, the author, who is an inspector of mines, gives a detailed account of several deposits of phosphatic minerals met with on and near the spot where the river Rhone enters French territory. The mineral, both mineralogically and palæontologically, differs from coprolites and phosphatic nodules, consisting, in fact, of shells, the interior of which is filled with phosphate of lime. A sample found at Lancrans gave on analysis, in 100 parts—Phosphate

of lime, 70.6; carbonate of lime, 15.0; insoluble matter, 12.0; bituminous matter and water, 2.4. A fragment from a nautilus from Mussel, gave, in 100 parts—Phosphate of lime, 65.3; carbonate of lime, 26.0; insoluble matter, 5.0; bituminous matter and water, 3.7. According to careful surveys, the total quantity of phosphatic mineral in this district amounts to 8,800,000 tons.

Although not strictly belonging to chemistry, we call attention to the following paper:—

Apiculture, a Method of Treating Bees for the Purpose of Safely Extracting the Honey and Wax from the Hives.—V. Meunier.—The author describes at length a process of administering chloroform to bees.

Absorbent Power of Phosphorus.—F. Sestini.—The author observes that when iodide of ethyl is made by Dr. Frankland's or Dr. Kopp's process there is left a solid brown-red to orange-brown residue, which is found to be amorphous phosphorus. The author says that this substance retains several metaloids, but especially iodine, even after having been repeatedly treated with boiling ether and then with a boiling solution of caustic potassa, while phosphuretted hydrogen is given off. There is left in the liquid much iodine; one sample was found to contain as much as 3.369 per cent. It appears, also, that the amorphous phosphorus (the residue from the preparation of iodide of ethyl) retains sulphur after having been treated with sulphide of carbon for the purpose of eliminating the ordinary white phosphorus; this sulphur is due to an incipient decomposition of the sulphide when in contact with the amorphous phosphorus at a higher temperature. According to the author, phosphorus exerts this absorbent power either by porosity (surface attraction) similar to that of charcoal and bone-black, or in the same manner as benzoic acid is retained by benzoin resin when the latter is used by the well-known process for the preparation of that acid.

Passivity of Cadmium.—M. Schoenck.—When cadmium is immersed in strong nitric acid (sp. gr., 1.47) it is readily dissolved, but when a spiral of platinum wire is tightly wound round the cadmium the latter is not acted upon by the nitric acid unless the acid is diluted with water.

International Congress for Weights and Measures.—M. Tresca.—The International metre will be constructed (viz., the standards) of an alloy of 90 parts of platinum and 10 of iridium, with a toleration of 2 per cent *plus* or *minus*; these standards will be verified at 0°, and copied exactly from the standards deposited in the Archives of the French Academy. The standard kilo. will be made of the same material, and also copied exactly from the standard deposited in the Archives of the Academy. The execution of the standards is entrusted to the French members, assisted by a permanent committee elected from the foreign members of the Congress; this committee will be composed of twelve members, five being a quorum. The members of the Congress have agreed to state to their respective Governments that it is desirable to establish a permanent International Bureau for Weights and Measures at Paris.

Polytechnisches Journal von Dr. E. M. Dingler, second number for September, 1872.

This number contains following original papers and memoirs relating to chemistry and collateral subjects:—

Improved Construction of Prony's Dynamometer.—C. Wersin.—The detailed description, illustrated by engravings, of an improved contrivance for ascertaining the dynamic force of machinery.

Peculiar Boiler Deposit Formed in the Steam-Space of a Boiler.—E. Mateczek.—The author relates a peculiar formation of a boiler deposit in the space not filled with water, but with steam. The sp. gr. of this material was found to be 1.388, and its chemical composition, in 100 parts, as follows:—Water, 2.831; fatty matter, 1.430; organic matter, 21.995; silica, 21.713; sulphuric acid, 6.947; chlorine, 0.139; oxide of iron, 3.836; phosphoric acid and alumina, 7.878; lime, 15.752; magnesia, 4.151; sand and clay, 12.283. The water used as feed-water for this boiler was taken from the river Elbe, but the large proportion of organic matter is in a measure due to the fact that the feed-water is taken from the condensed hot water from the air-pumps, the boiler being used in a beet-root sugar-works and refinery.

Estimation of Oxygen in the Decarbonised Bessemer Metal before the addition thereto of the Specular Iron, on the Action of that Iron and a Substitute for it, and the Means of Producing a Bessemer Casting without being Honey-combed.—Dr. A. Bender.—An essay strictly treating on the practice of sidero-metallurgy.

Journal für Gasbeleuchtung und Wasserversorgung, No. 18, 1872.

This number only contains matter relating to gas- and water-works' engineering and management.

NOTES AND QUERIES.

Transparent Cement.—(Reply to "Omica.")—You will find the information in the English edition of Wagner's "Chemical Technology," recently published by Messrs. J. and A. Churchill.

Oxychloride of Magnesium Cement.—Will any correspondent who has made this cement oblige by publishing the process; I have never been able to make it satisfactorily, nor have I met with anyone who has used it with success. The fact of its existence has been published so often as to leave no doubt of the possibility of making it.—T. F.

Sugar Refining—Works on Organic Chemistry.—(Reply to A. J. W.)—Consult "Traité Complet Théorique et Pratique de la Fabrication du Sucre Guide du Fabricant," par Charles Stammer (Paris: E. Lacroix). Among the large number of excellent works on organic chemistry published in different languages, we mention "Ausführliches Lehrbuch der Organischen Chemie," von Dr. H. Kolbe (3 vols.). These works may be inspected at the Patent Office Library. "Chemisch-Technische Mittheilungen," by Dr. Elsner; annually; 19 vols. published. "Jahresberichte über die Leistungen der Chemischen Technologie," by Dr. Wagner; 17 vols.; published annually. "Index to Foreign Scientific Periodicals contained in the Free Public Library of the Commissioners of Patents" (7 vols.).

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2476. A. Deiss, Plaistow, Essex, "A new or improved process of percolation for the purpose of extracting fatty, resinous, and similar matters."—Petition recorded August 20, 1872.

2712. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in effecting the purification of cast-iron, malleable iron, cast-steel, and malleable steel, and other metals or alloys."—A communication from J. B. L. Forquignon, Nancy, and L. M. Ehrmann, Paris, France.—Petition recorded September 12, 1872.

2746. E. T. Hughes, Chancery Lane, Middlesex, "The treatment of greasy and washing liquors used in scouring or cleaning wool by caustic baryta or strontia."—A communication from L. G. G. Daude-nart, and E. Verbert, Rue du Progrès, Schaerbeck, Brussels.—Petition recorded September 16, 1872.

2822. C. Morfit, Baltimore, U.S.A., "Improvements in the reclama-tion of materials employed in the manufacture of di-phosphate and tri-phosphate of lime."—Petition recorded September 24, 1872.

2913. H. B. Barnett and W. B. M. Slade, Gracechurch Street, London, "Improvements in the preparation or production of disin-fecting, antiseptic, and cleansing liquids."—Petition recorded October 3, 1872.

2930. J. G. N. Alleyne, Alfreton, Derbyshire, "Improvements in apparatus for the manufacture and refining of sugar and rum, or other spirit."

2934. H. B. Barnett and W. B. M. Slade, Gracechurch Street, London, "Improved manufacture of fluids for deodorising and disin-fecting purposes."—Petitions recorded October 4, 1872.

2941. G. Robbe, Fenchurch Street, London, "A medical prepara-tion applicable to the treatment of what is known as 'Foot and mouth disease' in cattle."—A communication from J. M. Brunet, Dieppe, France.

2943. E. J. Payne, Packwood, Warwickshire, and W. Clarke, Dud-ley, Worcestershire, "Improvements in converting or partially converting iron into steel."—Petitions recorded October 5, 1872.

2947. J. Macintosh, Bayswater, and W. Boggett, Chelsea, Middle-sex, "Improvements in treating and applying animal membranes, and in constructing articles therewith, comprising vessels to contain air, and in valves for inflating the same, which valves are applicable to other useful purposes."—Petition recorded October 7, 1872.

2959. W. Lorberg, North Bow, Middlesex, "A new or improved process for the manufacture of soap."

2964. H. Lonkin, Theydon-Gernon, Essex, A. Leighton, South Castle Street, Liverpool, and W. White, Thurlow Road, Hampstead, Middlesex, "Improvements in the production of iron and steel."—Petitions recorded October 8, 1872.

2974. B. Tanner, Liverpool, "Improvements in the manufacture of artificial manures."—Petition recorded October 9, 1872.

2982. J. Hargreaves and T. Robinson, Widnes, Lancashire, "Im-provements in the manufacture of alkalies, and in apparatus employed therein."

2989. J. Young, Kelly, Renfrewshire, N.B., "Improvements in the manufacture of carbonate of soda."

2995. J. H. Dickson, Harefield, Middlesex, "An improved process of and machinery for treating or preparing fibre-yielding plants for the purpose of obtaining useful fibres therefrom."—Petitions recorded October 10, 1872.

2997. J. W. Perkins, Brixton, Surrey, "The manufacture of artificial fuel."

3003. J. Steedman, Glasgow, N.B., "Improvements in obtaining acetic acid."

3005. C. Lowe, Reddish, Lancashire, "Improvements in the treatment of coal-gas tars for the purpose of obtaining certain useful products therefrom."

3007. E. C. Nicholson, Kennington Road, Surrey, "Improvements in the separation of substances and products capable of being em-ployed for the purposes of dyeing and printing."—Petitions recorded October 11, 1872.

3040. P. Maccallum, Dunfermline, N.B., "A new or improved arti-ficial fuel."—Petition recorded October 15, 1872.

NOTICES TO PROCEED.

1722. T. Gray, New Wandsworth, Surrey, "Improvements in the means of treating vegetable fibres for the manufacture of paper."—Petition recorded June 7, 1872.

1723. J. J. Harrop, Manchester, and W. Corbett, Bradford, Lancashire, "Improvements in puddling iron and in puddling furnaces."—Petition recorded June 7, 1872.

1742. C. A. Faure, Brook Street, Lambeth, Surrey, "Improvements in the process or processes of applying electric currents to chemical decompositions and combinations, including the manufacture of alkalies."—Petition recorded June 10, 1872.

1743. O. Doyen, Reims, France, "An improved preparation and utilisation of coffee in the form of tablets for food."—Petition recorded June 10, 1872.

1760. J. Dupont, Nimes, France, "The application and treatment of certain plants not hitherto used for the production of filaments and fibres."—Petition recorded June 12, 1872.

2144. S. S. Bateson, Bolton Street, Mayfair, Middlesex, "Improvements in the treatment of hides or skins."—Petition recorded July 17, 1872.

2712. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in effecting the purification of cast-iron, malleable iron, cast-steel, and malleable steel, and other metals or alloys."—A communication from J. B. L. Forquignon, Nancy, and L. M. Ehrmann, Paris, France.—Petition recorded September 12, 1872.

2790. R. Stone, Liverpool, "An improved artificial fuel."—Petition recorded September 20, 1872.

2845. F. Walton, Staines, Middlesex, "Improvements in oxidising oil, and in machinery to be employed for that purpose."

2847. C. W. Harrison and A. H. Harrison, High Holborn, Middlesex, "Improvements in combining atmospheric air and certain gases for lighting and heating purposes."—Petitions recorded September 26, 1872.

2861. C. W. Siemens, Great George Street, Westminster, "Improvements in the process for the production of iron and steel, and in furnaces or apparatus employed for that purpose."—Petition recorded September 28, 1872.

2930. T. Greener, Darlington, and W. Ellis, Gateshead, Durham, "Improvements in the manufacture of iron and in the production of 'fetting' for improving the quality and yield of iron in the process of reduction."—Petition recorded October 7, 1872.

2964. H. Larkin, Theydon Gernon, Essex, A. Leighton, South Castle Street, Liverpool, and W. White, Thurlow Road, Hampstead, "Improvements in the production of iron and steel."—Petition recorded October 8, 1872.

PATENTS SEALED.

1171. J. Barrow and C. J. Crosfield, Liverpool, "Improvements in utilising certain saccharine syrups, and in apparatus employed therein."—Dated April 10, 1872.

1264. W. A. Lytle, Hammersmith, Middlesex, "Improvements in the preparation and utilisation of bituminous asphalt."—Dated April 27, 1872.

1293. C. Duff, Wandsworth Road, Surrey, "Improvements in the treatment of fibrous substances to be used in the manufacture of pulp for paper, and for conversion into spun and textile fabrics."—Dated April 30, 1872.

1307. L. Bradley, Rotterdam, Holland, "Improvements in the manufacture of cement."—Dated May 1, 1872.

1468. J. Spratt, Camberwell, Surrey, "A new or improved food for cats."—Dated May 14, 1872.

1476. R. C. Menzies, Valleyfield, Midlothian, N.B., and A. E. Davies, Worcester, "Improvements in the manufacture of pulp for paper-making."—Dated May 15, 1872.

1802. C. W. Smith, Highfield, near Stroud, Gloucestershire, "Improvements in the extraction of indigo and other similar substances from plants containing such substances."—Dated June 15, 1872.

2572. W. R. Lake, Southampton Buildings, London, "Improved compounds, chiefly designed for coating ships' bottoms."—A communication from J. H. Bloodgood, New York, U.S.A.—Dated August 29, 1872.

FOREIGN PATENTS.

ITALY.

1. L. Pasteur, "A new process for the manufacture of beer."—Dated September 4, 1871.

3. J. V. P. Lagrange, "Purifying and clarifying sugar-juice and syrup in sugar works."—Dated December 11, 1871.

4. E. Leconte, "Using starch of maize, rice, &c., in the manufacture of beer, alcohol, and other fermented liquors."—Dated January 2, 1872.

Chemical Technology, or Chemistry in its

Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE and Co., 20, King William Street, Strand.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

THE LABORATORY will be open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

THE CLASSES will meet as usual.

THE CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

THE LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

THE MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

THE BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under $\frac{1}{4}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{4}$ per cent.

VOL. XXVI. No. 676.

DESCRIPTION OF A NEW QUINIMETRIC PROCESS.*

By P. CARLES.

HAVING ascertained, by experiment, that the quinimetric methods in use are not suited for extracting, in a sufficiently pure state to admit of weighing, all the quinine contained in the cinchona barks (the decoction method extracts colouring matter and changes the active principles, while the lixiviation process yields very weak liquors, in which a portion of the alkaloids are kept in solution), I have devised a method which may be carried out as follows:—A good average sample of the bark is ground to powder, and passed through a fine horse-hair sieve; 20 grms. of this powder are intimately mixed with from 6 to 8 grms. of slaked lime, mixed with 35 grms. of water, and the mixture of quina bark and pasty lime dried at a gentle heat; the cake thus formed is reduced to a coarse powder and pressed into a conically-shaped glass tube (or a funnel with stop-cock and glass stopper); chloroform is then gradually poured on to the contents, care being taken to cork the tube at the top: 150 grms. of chloroform will be a sufficient quantity, but it is best to ascertain if the bark is exhausted by evaporating a few drops of the last portion of the chloroform in a porcelain basin; the residue should be treated first with dilute sulphuric acid, and next with chlorine water and ammonia. The chloroform which adheres to the mixture of lime and bark is displaced by the addition of water, and the fluid is next evaporated upon a water-bath until a dry residue is left. If desired to save the chloroform, it can be distilled off in a retort upon a water-bath: the distillation should not, however, be carried on to dryness, but the remainder of the fluid is to be evaporated to dryness in a porcelain capsule, and then treated with dilute sulphuric acid. The solid dry residue consists of the alkaloids of the bark, mixed with about their own weight of waxy-resinous (*céréo-resineux*) matters; the alkaloids are taken up by dilute sulphuric acid (1 to 10), of which fluid from 10 to 12 c.c. are sufficient. This solution is filtered through a very small, previously moistened, filter, and the filtrate is colourless; the filtrate is next heated to 100° upon a water-bath, and, when hot, ammonia—at first concentrated, afterwards dilute—is added, so as to cause the filtrate to become very nearly saturated,—to be left very slightly acid; all the quinine will then crystallise in the shape of sulphate. This crystallisation proceeds rapidly, and the peculiar odour emitted by the fluid, as well as the aspect of the crystals, are of some value in ascertaining beforehand the quality of the bark operated upon. When the liquid has become completely cold the crystalline matter forms a solid cake, which has only to be placed upon a double filter for the purpose of draining; the mother-liquor is displaced by a few drops of water, after which the mass is gently pressed, dried, and weighed.* If the mother-liquor is found to be very acid, ammonia in slight excess should be added, for the purpose of precipitating the rest of the quinine. The other alkaloids remain in solution, and are next separated by precipitation, dried, weighed, and tested with washed ether.

This process is simple and expeditious, and yields good results, the quinine being obtained in a colourless state. I quote the following instances of its working:—(1).

* *Bulletin de la Société Chimique de Paris.*

† It is preferable to dry at 100°, and, after having weighed, to add the 12 per cent of water lost by the operation: in that condition it contains 75 per cent quinine.

A mixture was taken of pure sulphate of quinine, 0.60; cinchonine, 0.20; dilute sulphuric acid (1 to 10), 10 c.c.; while hot I poured, by means of a pipette, first concentrated and then dilute ammonia nearly to saturation: result obtained—sulphate of quinine, 0.59; cinchonine, 0.22. (2). Sulphate of quinine, 0.50; cinchonine, 0.25; acid at 1.10, 10 c.c., found sulphate of quinine, 0.52; cinchonine, 0.17. A. Yellow cinchona bark, 20 grms. has yielded per 1000, by the use of Rabourdin's modified process (see *Journ. de Pharmacie*, 1861), strongly-coloured crystalline sulphate of quinine, 23.00; with Le Maitre's process, somewhat yellow-coloured sulphate of quinine, 22.30; with my process, colourless sulphate of quinine, 26.55. B. Yellow cinchona bark, same quantity, by Rabourdin's process, strongly coloured crystallised sulphate of quinine (per 1000), 29.50; Le Maitre's process, yellow-coloured sulphate, 26.75; my process, colourless sulphate, 31.25. Trials with other kinds of bark yielded similar results, but I should mention that the separation of the quinine as sulphate only succeeds well when the quantity of quinine in the bark greatly exceeds the cinchonine.

To exhibit the effect of an excess of cinchonine I quote the following:—Sulphate of quinine, 0.40; cinchonine, 0.60; acid 1.10, 10 c.c., yielded—sulphate of quinine, 0.58 (mixed with cinchonine); cinchonine, 0.48: the impure sulphate of quinine thus obtained may be purified, recrystallised, and tested with ether and ammonia.

As sulphate of quinine is completely insoluble in a solution of sulphate of ammonia, there is no fear of any of the sulphate of quinine being left in the mother-liquor if the saturation with ammonia is sufficiently complete. To prove this experimentally, take a small quantity of sulphate of quinine, shake it up in a test-tube three parts filled with cold distilled water, filter, and add to the filtrate a few crystals of sulphate of ammonia. After a few minutes the liquid will become a pasty mass: this is filtered, and not a trace of sulphate of quinine is found in the filtrate.

ON SLOW COMBUSTION.

By P. J. Van KERCKHOFF, Ph.D., &c.,

Professor of Chemistry at the University of Groningen, Netherlands.

A LARGE number of substances possess the property of combining, in a shorter or longer period of time, according to the prevailing conditions, with oxygen, and form therewith oxidised compounds. In many instances this slow or rapid oxidation depends (all other conditions remaining unaltered) upon the temperature, but it is not the only factor. To the large number of conditions which influence oxidation belongs the presence of a substance which is found unaltered after the action is finished; this substance may or may not have undergone any action at all. Many of these actions, formerly known as action of contact, or catalytic action, have become better known by deeper investigation; it has been ascertained that they could be reduced, either to ordinary chemical actions, in which the active substance became alternately metamorphosed and reproduced, or to modifications of physical conditions implying generally a change of temperature. To the alternate fixation and giving off of oxygen belongs, for instance, the action of deutoxide of nitrogen and of ferric oxide; to the second, the remarkable property of platinum, first discovered by Sir Humphrey Davy, to determine chemical combinations in general, and consequently also oxidations, while the platinum itself is not chemically altered. This property of platinum has led to experiments with other substances, many of which were found to act in a manner similar to platinum. The researches of Döbereiner, Pleischl, Dulong, Thénard, Cloez, and others have brought to light a great many facts relating to this subject. As, however, the conditions which play a part in the

phenomenon alluded to, and the influence of which ought to be known, have not all been thoroughly taken into account, it appeared to me that the study of some of them would not be useless. I have limited my investigation to the action of oxygen upon a couple of combustible gases—viz., (1) on a pure (unmixed) gas, oxide of carbon; and (2) on the mixture of gases constituting ordinary illuminating gas, care having been first taken to completely eliminate all the carbonic acid. The following principal points were investigated:—

(1). What degree of influence is exerted by the time of duration of the contact between the combustible gas and oxygen, in the presence of chemically passive matter.

(2). Whether this duration varies according to the nature of the solid matter.

(3). Whether, for different gas mixtures, the slow combustion requires a different temperature.

(4). Whether the carbonic acid, which must be generated in the case of oxidation, is evolved in the state of gas, or remains condensed in the porous matter.

(5). Lastly, among the solid substances in the presence of which the combustion can proceed, I have chosen one which hitherto has scarcely been investigated, and could be used in pure state without carrying over oxygen to the combustible substance.

My first experiments were so arranged that a mixture of oxygen and combustible gas, each of these being previously freed from any trace of carbonic acid, was slowly passed through a U-shaped tube containing the solid material to the influence of which it was desired to submit the gaseous mixture. The gas, after having passed through the U-shaped tube, was conveyed through clear lime-water. The U-tube could be placed, if required, in a water-bath, so as to keep up any degree of temperature desired. The oxygen, prepared from chlorate of potassa and collected in a gas-holder over pure water, was in every experiment passed through a tube containing soda-lime, in order to eliminate any carbonic acid or chlorine with which it might accidentally be contaminated; then it was passed through a large bottle containing lime-water. The same precautions were taken with the oxide of carbon, prepared by the action of sulphuric acid upon oxalic acid, the gas being thoroughly washed through milk of lime previous to being conveyed to the gas-holder, the tank of which was also filled with thin milk of lime. The ordinary illuminating gas, which nearly always contains traces of carbonic acid, was, of course, purified. In all the experiments, the gas, on being tested previous to its passage through the U-tube, was found to be free from carbonic acid.

The solid substances employed in these experiments are—(1) platinised asbestos previously ignited; (2) pumice stone, first repeatedly boiled in dilute hydrochloric acid, next well washed, and lastly ignited; (3) pipe-clay treated in the same way. Repeated experiments taught that, between temperatures varying from 5° to 15°, platinised asbestos was the only one of the three substances which caused the oxidation of the oxide of carbon. The mixture caused, after having passed the asbestos, in a relatively short time, a precipitate in the bottle containing lime-water; but in the case of pumice-stone and pipe-clay not the slightest turbidity was observed. This result with the platinised asbestos could be readily foreseen, as it is well-known that spongy platinum even causes the deflagration of a mixture of oxide of carbon and oxygen, especially when these two gases are mixed in the proportion of 2 vols. of CO for 1 vol. of O. By the use of platinised asbestos the action is slackened sufficiently by the state of division of the platinum between the fibres, that no explosion of the gases takes place. When a mixture of 1 vol. of illuminating gas and 2 vols. of oxygen were caused to pass, at a temperature of from 5° to 15°, through the U-tube filled with platinised asbestos, not a trace of carbonic acid was formed. Similar experiments were made with pumice-stone and pipe-clay, first at a temperature of from 50° to 60°, next at between 80° and 90°, but in neither of these

operations was any carbonic acid formed. As an instance of the mode of operating and experimenting, I quote the following description of an experiment:—

Coal-gas and oxygen, both quite free from carbonic acid, were mixed in the proportion of 1 vol. of the first and 2 vols. of the second, and passed through a U-shaped tube of about 10 c.c. capacity, filled with 5 grms. of purified pipe-clay; the tube was placed in a water-bath kept at a temperature of from 50° to 60°. The velocity of the current of the gas was so regulated that the outlet-tube, having an internal diameter of 5 m.m., passed four bubbles of gas per second, while the operation was kept going on for half an hour; neither during this time, nor after it, was the slightest turbidity caused in the lime-water, through which the gas was passed when leaving the outlet-tube.

Judging from the results of experiments to be presently mentioned in detail, it might be suspected that a small quantity of carbonic acid, which might have been formed at the temperature alluded to, could have been retained in the U-shaped tube by the pipe-clay. In order to ascertain this, the gaseous mixture retained in the tube was first expelled by a current of air previously freed from carbonic acid at the ordinary temperature, and the tube next heated up to nearly 100°, while the current of air was kept up. Even after this operation the lime-water remained perfectly clear.

In the second series of experiments, made with the same mixture of combustible gas and oxygen, the duration of the contact with the solid substance has been much prolonged, and consequently the arrangement of the apparatus was different. The gases intended to be experimented with were mixed and measured in the proportion of 2 vols. of CO and 1 vol. of O, or of 1 vol. of coal-gas and 2 vols. of O, in a glass bell-jar fitted with a stop-cock, and placed over lime-water; by forcing the bell-jar down into this fluid the gas could be forced out of it. This gas mixture was next made to pass through a tube filled with soda-lime, and next through a bottle containing lime-water, which, in order to make the experiment reliable, ought to remain quite clear, and this was so in all the experiments recorded. A glass vessel of about 600 c.c. capacity, and fitted with two necks, is filled with the gas mixture, care being taken to cause the gas to pass for some time slowly through the vessel for the purpose of eliminating the air it contains. Into each of the necks is tightly fitted a cork, which is varnished, and into each of which a short glass tube is fitted tight; a stout vulcanised india-rubber tube is tied to each of them. By means of a spring-clip these tubes can be closed if desired.

The balloon-shaped glass vessel, into which some 5 to 6 grms. of the solid substance (after being ignited) to be experimented with has previously been placed, having been well filled with gas, and the inlet- and outlet-tubes closed, could be kept at the desired temperature without any chance of atmospheric air being introduced into it, as proved by the negative results of several of the undermentioned experiments. To ascertain, at the end of the experiment, whether oxidation had or had not taken place, the contents of the balloon were tested as follows:—One of the caoutchouc tubes fastened to the neck of the balloon was connected with a test-bottle filled with lime-water, to which was further connected a tube filled with soda-lime, through which the atmospheric air, intended for the purpose of displacing the gas contained in the balloon, had to pass. To the other caoutchouc tube was fastened a glass tube, destined to carry off the gas from the balloon into lime-water, contained in a double-necked bottle and connected with an aspirator. In this manner, it was possible to regulate at will the rapidity of the current of the air from the balloon into the lime-water. Although there could be no doubt that platinised asbestos would, in this mode of experimenting, just as in that above referred to, cause oxidation, we have again tried it, and pumice-stone and pipe-clay have also been used. Each of the following experiments has been repeated, always with the same results:—

Experiments made with Oxide of Carbon.

Temperature, 0° to 10°. Duration of experiment, 16 days.

Lime-water.

Platinised asbestos Yields a turbidity after the passing of a few bubbles of gas, and afterwards an abundant precipitate.

Pumice-stone .. Remains quite clear.

Pipe-clay Remains quite clear.

Temperature, 5° to 15°. Duration of experiment, 16 days.

Lime-water.

By passing the gas of the balloon into it without application of heat—

By passing air into the balloon after the gas has been eliminated, the solid substance being simultaneously heated—

Pumice-stone { Remains quite clear. } Remains quite clear.

Pipe-clay..Remains quite clear. Remains quite clear.

Temperature, 50° to 60°. Duration of experiment, 9 hours.

Lime-water.

The gas being passed into it without the contents of the balloon having been heated to a higher degree.

Pumice-stone .. Soon gives a precipitate, which in a short time becomes considerable.

Pipe-clay Remains quite clear.

Temperature, 64° to 65°. Duration of experiment, 16 hours.

Lime-water.

By passing the gas from the balloon into it without further heating the contents—

By passing air through the balloon after the gas has been withdrawn from it, and simultaneously heating of the solid substance—

Pipe-clay { Remains perfectly clear. } Causes soon a turbidity, which increases after a short time.

Temperature, 80° to 90°. Duration of experiment, 12 hours.

Lime-water.

By passing the gas from the balloon into it without further heating the contents—

By passing air through the balloon after the gas has been withdrawn from it, and simultaneously heating the solid substance—

Pipe-clay { Remains perfectly clear. } Becomes rapidly and rather strongly turbid.

Experiments with Coal-Gas.

Temperature, 5° to 15°. Duration of experiment, 9 days.

Lime-water.

By passing the gas from the balloon into it without further heating of the contents—

Pumice-stone .. Remains clear.

Pipe-clay Causes a perceptible turbidity.

Temperature, 80° to 90°. Duration of experiment, 11½ hours.

Lime-water.

By passing the contents of the balloon into it without further heating the contents—

By passing air through the balloon after the gas has been withdrawn from it, and simultaneously heating the solid substance—

Pumice-stone— Causes a perceptible turbidity. Becomes strongly turbid and gives a precipitate.

Pipe-clay— Becomes immediately turbid and gives a precipitate. Not examined.

As regards the experiments with platinised asbestos, I have only to observe that, under its influence, which becomes apparent at the ordinary temperature, coal-gas is burnt less easily than oxide of carbon by oxygen; and it appears that, in the first place, the small quantity of oxide of carbon, contained to an amount of from 7 to 9 per cent in coal-gas, is first oxidised. Leaving out of the question the action of the platinised asbestos, the following conclusions can be drawn:—

(1). That at the ordinary temperature a pumice-stone and pipe-clay cannot, when the time of action is short, cause the oxidation of oxide of carbon, nor of coal-gas when mixed with pure oxygen.

(2). That a contact of brief duration does not produce any perceptible oxidation at temperatures of from 50° to 60°, and even at from 80° to 90°.

(3). That, while the combustion of these two gases is not perceptible when the experiment lasts only a short time, it becomes very perceptible when the experiment is continued for some length of time; it is, therefore, not improbable that, when the experiments were continued for a long time, oxidation would be ascertained to take place where during sixteen days no formation of carbonic acid occurred.

(4). That oxidation or combustion, resulting in the formation of carbonic acid, requires the longer time when the temperature is low.

(5). That there exists a difference between the temperatures at which pumice-stone and pipe-clay begin to exert an influence upon the oxidation of oxide of carbon, pumice-stone becoming active earlier than pipe-clay when the temperature increases.

(6). That, as regards coal-gas, an inverse relation is observed, because pipe-clay already manifests activity at a temperature at which pumice-stone, left in contact with the gas mixture for the same time, does not give rise to oxidation.

(7). That the carbonic acid gas which is formed does not always make its appearance at once as a gas in free state, but may remain entirely occluded in the pores of the solid substance when the quantity of gas operated with is small.

(8). That pipe-clay retains the carbonic acid gas which is formed far more readily than pumice-stone, while the former also only gives it off at a higher temperature.—*Archives Néerlandaises des Sciences Exactes et Naturelles.*

NOTE ON CHLORAL.

By EDWARD R. SQUIBB, M.D.

CHLORAL supplies another forcible illustration of the baneful effects of speculation and inflation, and of the dangers which must always attend popularity, and particularly the popularity of potent medicinal agents. It seems hard to teach the public that nothing can be potent only for good. That to be potent for good involves, in the very nature of all things, an equal potency for harm. Hence the danger of advertising any medical substances which have any potency for popular use. The multitude of mere placebos, and catch-penny quackeries, which serve at the same time to make money and give mental occupation and relief to trifling or imaginary ills, may be puffed and inflated for popular use with comparative safety. But when this same process is applied to a potent agent like chloral, the chances are always greatly in favour of the substance doing more harm than good, until a panic and a prejudice are produced against it, when it may be unjustly condemned and lost.

The definite results from the careful and proper use of chloral, and its great importance in filling a place in therapeutics hitherto vacant, fortunately secure it against being lost by this reaction; and it is perhaps well, therefore, that by the sacrifice of a few lives at the outset of its career, many lives may be saved, and its use be

restricted to the hands of physicians. Pharmacists cannot be too careful how they advise or dispense such agents for popular use, and they will undoubtedly be, sooner or later, held responsible for all the misuse to which their commodities may be applied.

The experience and education obtained in the making of some 1500 lbs. of chloral within the past year have served to improve the writer's knowledge of this important substance, and may justify him in offering some remarks upon its characteristics and tests.

Since it has become easier to make the hydrate than the alcoholate of chloral, the latter, and all mixtures of it, have practically disappeared from the market without any probability of their ever re-appearing. This renders the tests for alcohol and alcoholates unnecessary.

When the water of hydration is in excess, or when solid compounds of hydrate of chloral and water are put up, the substance is deliquescent, or even melts in warm weather, and a very slight excess of water manifests itself very soon by some degree of deliquescence. Whether in cake or crystal, it is now very generally put up slightly deficient in water of hydration; that is, the chloral is not fully saturated to the condition of a full hydrate, and under proper control this is the best practice yet arrived at by the writer. If it could be exactly saturated, that of course would be best; but, as this seems not easily practicable it is best to have the water a little short of full hydration. If more than a shade short, however, the hydrate is proportionally pungent, because anhydrous chloral is much more pungent than the hydrate. Another disadvantage of the presence of free or anhydrous chloral is, that it renders the hydrate which contains it more liable to become slightly acid. These circumstances, and the fact that under varying conditions chloroform dissolves more or less water, and watery solutions dissolve more or less chloroform, together render the chloroform test fallacious and comparatively useless as ordinarily applied. That is, the yield of chloroform may be always the same if the decomposition be complete, but it cannot be weighed or measured with sufficient accuracy.

Chloral has now been made in such quantities, and with so much competition, and it is so comparatively easy to make it of fair quality, that the mistakes and imperfections arising from ignorance are now no longer made, and the general quality has got far beyond the reach of the earlier tests. More sensitive and more delicate tests are now needed—not to decide whether a given substance is hydrate of chloral, but to decide between different specimens of hydrate of chloral which come into the markets, even from the same manufacturer—as to which contains the least or the most of other and mere accidental products of the action of chlorine on alcohol. In all the better brands these accidental products are in very small proportion, and not easy of detection. Just as in the instance of chloroform, they are neither made nor left in it purposely or carelessly, and the defect lies simply in the insufficiency of the means and the labour necessary to take the last portions out. Within practical limits they may all be taken out by any of the processes in use for the purpose, provided these be used with sufficient skill, pains, and labour; and the want of uniformity of the best brands now in the market is chiefly due to want of care and labour. That is, profit being the chief object, this is increased by dodging its greatest enemy, namely, skilful labour.

After a large number of examinations, the writer comes to the conclusion that at present there is no single test which will indicate the quality of chloral, and that the value of any group of tests depends almost entirely upon the skill and care with which they are applied. The sensible properties are very characteristic to those who are expert and familiar with the substance, and by a little education and practice any one may soon attain a pretty critical judgment.

The writer still greatly prefers the granular crystalline form to any other, as conducive to greater purity, and the

most simple and critical mode of examination known to the writer, and which has not been hitherto published, is by means of chloroform. Chloral and its hydrate are both freely soluble in chloroform, and from this solution, when dropped on bibulous paper or evaporated from a watch-glass, the chloroform flies off first, the anhydrous chloral next, and the hydrate last and more slowly. The impurities are still less volatile, and may be detected in the later stages of the evaporation by their different odour. The hydrate of chloral, after the last traces of anhydrous chloral have passed off, is comparatively inodorous, and what odour it has is very mild, sweet, and clean, so that any contamination of this mildness and sweetness is the more easily recognised. The chloroform used must of course be itself free from much impurity, and should not colour sulphuric acid. The solution of chloral in chloroform, when tested with sulphuric acid, just as chloroform is tested, should give no colour to the acid. The acid should be poured slowly into the chloroform solution, when the slightest change of colour can be seen at the line of separation between the two liquids before they are shaken together. Indeed, after shaking, the coloured stratum becomes so diluted by the excess of acid, that the tint may be hardly recognisable. So delicate is this test that, when carefully and properly managed, no specimen of chloral has ever been seen, except when taken directly from the purifying flasks, that would not give some colour at the line of separation between the liquids. That is, the atmospheric dust, which is unavoidable in the handling and putting up of the chloral, is sufficient to give a tinge at the line of separation. As in the case of chloroform alone, the colour, however much or little, increases by standing, and is only fully developed after twenty-four hours. In this testing the chloroform alone should be tested, side by side with the chloroformic solution of chloral, and only the difference be taken into account. Of course colourless concentrated sulphuric acid should be used, and a chemically clean glass-stoppered bottle, as in the testing of chloroform.

The next important step in the examination, not hitherto published, is the freezing-point, or the temperature at which the chloral begins to crystallise when melted. This point appears to be very definite, and is very easily ascertained. An ounce bottle of chloral, as purchased, should have the glass stopper loosened, but not removed (it should never be sold in any other than glass-stoppered bottles), and the bottle should be then immersed to the shoulder in warm, not hot, water, and occasionally shaken until the chloral is melted. The liquid chloral should, of course, be colourless, transparent, and free from specks of foreign matter to a practical degree. The bottle should then be taken from the warm bath, the stopper removed, and, while held by the neck, the bulb of a small chemical thermometer should be placed in the liquid and used continuously as a stirrer until the liquid becomes opalescent or loses its bright transparency. At this moment the temperature should be taken and noted. The bottle is then again placed in the warm water, and the contents stirred until again transparent; then again removed from the bath and again stirred to the crystallising point, and the temperature again noted for verification of the first trial. This does not waste nor injure the chloral at all, and the thermometer, when removed, should be immersed in distilled water in a small test-tube, to dissolve off the adherent chloral. The solution thus obtained, if tested with pale blue litmus-paper, will commonly indicate slight acidity, and with solution of nitrate of silver will give slightly more cloudiness than the water alone will give. The writer has never tested a specimen of chloral which had been six months made, which did not give evidence of slight hydrochloric acid acidity, if the testing was delicate. Hence it is not amiss, though perhaps not important, to add a drop or two of ammonia to all solutions of chloral when dispensed for use, as originally advised by Liebreich, since it may serve to arrest a commencing decomposition which might soon become rapid in the

solution, particularly when the solution is to be kept many days, or when it has organic matter of any kind in it.

To return to the freezing-point. Specimens of chloral from the best makers may be found in the market, which begin to crystallise at from $45^{\circ}\text{C.} = 113^{\circ}\text{F.}$, up to $52^{\circ}\text{C.} = 125.6^{\circ}\text{F.}$ The best specimens, however, crystallise between $48^{\circ}\text{C.} = 118.4^{\circ}\text{F.}$, and $51^{\circ}\text{C.} = 123.8^{\circ}\text{F.}$ Those which crystallise at the higher temperatures contain the most anhydrous chloral, and those which crystallise at the lower temperatures contain an excess of water. Accurately hydrated chloral crystallises at about 48° to $49^{\circ}\text{C.} = 118.4^{\circ}$ to 120.2°F. , and the best practically adjusted specimens crystallise within one-half a degree of $50^{\circ}\text{C.} = 122^{\circ}\text{F.}$ Specimens which crystallise below $48^{\circ}\text{C.} = 118.4^{\circ}\text{F.}$ do not stand summer temperatures without becoming moist, whilst those which crystallise below $47^{\circ}\text{C.} = 116.6^{\circ}\text{F.}$, are proportionately deliquescent. This tendency to deliquesce is, however, mainly due to the interstitial mother-liquid, and this liquid it is which absorbs the moisture of the atmosphere, and thus finally dissolves the crystals in warm weather. Hence, as large crystals can only be obtained by comparative slow crystallisation from more dilute solutions, they contain the most watery liquid in the interstices, and therefore soonest deliquesce. A basin of large crystals, looking somewhat like bromide of potassium, in regard to the size of crystal, stood upon the writer's table covered loosely with paper, from March until September. Up to the 1st of June they remained quite dry, and could be powdered as easily as bromide of potassium. They then began to grow moist, slowly at first, but very rapidly during the latter part of July, and now in September there is a confused mass of crystals at the bottom of the capsule, covered by an inch or more of transparent syrupy liquid.

A few pounds of these same crystals standing in the same place, in an imperfectly stoppered, wide-mouthed bottle, and this frequently opened, have kept much better, and are in fair condition, though moist. Small granular crystals, which form from the melted chloral when carefully underhydrated, seem to be by far the best form for convenient practical use.

All the writer's experiments, and they have been numerous, of crystallising from bisulphide of carbon, from ether, from chloroform, and from oil of turpentine, have failed in practicability.

Another important test of quality for commercial chloral is its boiling-point. This was early recognised as a test, because no two liquids are known which boil at precisely the same temperature, while all mixtures are known to have a moving boiling-point, that is, do not boil continuously at any fixed temperature. Writers, however, have given a very different value and significance to this test, some regarding it as no test at all, while others have considered it infallible. This discrepancy appears to depend upon the skill or want of skill and knowledge with which the test was applied. Most liquids can be heated far above their boiling-point without boiling, but all can be made to boil at the normal boiling-point by proper management. Chloral simply heated in a clean test-tube may, or may not, boil at its boiling-point. But if the test-tube be one-sixteenth filled with broken glass, and be heated in a glycerine bath, the chloral will boil at its normal boiling-point, and will continue to do so, and a chemical thermometer immersed in it will indicate the boiling-point with accuracy.

Accurately hydrated chloral begins to give off bubbles of vapour from the hottest surfaces of the tube when the thermometer indicates about $90^{\circ}\text{C.} = 194^{\circ}\text{F.}$, but it does not properly boil throughout the liquid below $97^{\circ}\text{C.} = 206.6^{\circ}\text{F.}$, and one-half of it at least will boil off before the temperature varies much from this point. It however appears to gradually decompose from air contact, or some other cause, underhydrated chloral boiling off, and overhydrated chloral remaining, so that the boiling-point gradually rises after boiling for some time. The best commercial specimens of chloral—that is, a little

underhydrated—begin to boil throughout the liquid at about $96.5^{\circ}\text{C.} = 205.7^{\circ}\text{F.}$ The underhydrated portion, however, boils off in a few seconds, and the thermometer rises to $97^{\circ}\text{C.} = 206.6^{\circ}\text{F.}$, and finally to 97.5° or $98^{\circ}\text{C.} = 207.5^{\circ}$ or 208.4°F. , by the time that half the liquid has boiled off.

Chloral should not begin to boil fairly below $95^{\circ}\text{C.} = 203^{\circ}\text{F.}$, because if it does it is too much underhydrated, and therefore too liable to decomposition; and it should boil down to one-half steadily at 97° to $98^{\circ}\text{C.} = 206.6^{\circ}$ to 208.4°F. If it boils off above $98^{\circ}\text{C.} = 208.4^{\circ}\text{F.}$, the indication is that it is overhydrated and deliquescent.

The natural accidental impurities which are left in the chloral are, in all the better grades, in so small a proportion as to escape detection by any ordinary application of the boiling-point test.

In conclusion, it may be remarked that, while several of the grades of chloral now to be found in the market are worthy of confidence, they are by no means uniform, but are improving in this respect; and there is no reason to fear that good chloral will ever again be accessible at a moderate price. The enormous scale upon which it has been made in Germany, and the difficulty of reducing this scale to meet the reaction which fatal cases of poisoning in popular use has caused, have overstocked and very much depressed the market; and it is to be feared that some of this overstock may become decomposed before it can be consumed. The quality should therefore be closely watched, and as soon as a parcel is found to be strongly acid it should be rejected. The test of acidity by means of a glass rod wet with solution of ammonia held near the mouth of the bottle, though useful, is not entirely trustworthy, and is hypercritical, since the vapour of anhydrous chloral, whether of itself or by slight decomposition from air contact, produces a cloud with ammonia.

ON THE STYLE OF GAS-BURNER FOR BENDING GLASS TUBES.

By H. CARRINGTON BOLTON.

PROFESSOR J. LAWRENCE SMITH, in a note "On Bending Glass Tubes for Fitting Apparatus" (CHEMICAL NEWS, vol. xxv., p. 175), recommends a Bunsen burner flattened at its extremity so as to give a thin broad flame. This is certainly a great improvement on the commonly employed burner, but an ordinary fish-tail or bat-wing gas-burner will be found to give, if possible, still better results. The writer has employed for some years an ordinary bat-wing burner attached to a small, short stand (3 inches high, burner included), so as to rest low upon the table, in order that raising the arms inconveniently high may be avoided. Such a burner insures a broad flame, by which the tube is heated for two or more inches in length; the tube is turned while in the flame, and removed for bending as usual.

The deposit of carbon, which, at first sight, might seem an objection, is really one of the chief advantages of using this burner. On placing the glass in the flame, the deposit begins immediately and prevents too rapid a rise of temperature and consequent cracking of the glass; during the heating the carbon tends to distribute the heat equally over the surface of the tube; and, finally, on withdrawing the glass from the flame too sudden cooling is prevented, and the glass is, as it were, annealed.

The black deposit is readily removed by a dry cloth. This plan was commonly employed in Hofmann's laboratory, Berlin. In bending tubes of more than three-eighths of an inch in diameter, one end should be closed tightly with a cork (or wax) and air blown into the other end at

the moment of bending the tube; by regulating judiciously the pressure of the air upon the sides of the somewhat softened tube, the latter will neither bulge out nor collapse, but will retain its proper calibre. This cannot be effected, however, with very large tubes, or with very thin ones, which require the nice manipulation of the professional glass-blower.—*American Chemist.*

ON THE ECLIPSE EXPEDITION, 1871.*

By J. NORMAN LOCKYER, F.R.S., M.R.I.

I UNDERSTAND my duty to-night to be to give an account of the observations made, not by all who observed the eclipse of last December, but by the members of the party which went out under the auspices of the British Association, and it is extremely fortunate that nothing more is required of me—first, because most valuable work was done by the other parties, which of itself would require more time to state than I have at my disposal; and secondly, because the amount of material obtained by the members who were sent out from England, and by the friends who met them at every point, is so great, that it would be impossible in one discourse to give anything like an exhaustive account of it. Here are some of the records in this portfolio. You will see at once that even for one party I can only make a selection, and I am perfectly aware of the extreme responsibility which attaches to anyone who may venture to make a selection out of such an enormous mass of material as we have collected.

Before I proceed to discuss the work done by the different parties, it will be desirable to give an idea of the arrangements, and for this purpose I have prepared several maps, which will enable you to see what the British Association parties did.

In the first instance, I may remark that the weather conditions were somewhat problematical. Another point of great importance was that much of the ground was fortunately occupied, and it was essential, when placing the parties, to bear these two considerations in mind—the possibility of bad weather; and then the importance of so arranging matters that, if some of the observers were clouded out belonging to our parties, then the story might be continued by other observers.

Here we have a map of India, which gives you a general idea of the path of the shadow during the eclipse. The shadow, you see, strikes India on the western coast, and it runs down in a south-westerly direction and cuts the northern portion of Ceylon.

When we arrived in India we found that the Indian observers, consisting of those well-known men, Tennant, Herschel, Hennessy, Pogson, and others, had determined, from their knowledge of the climatic conditions of India at that time of the year, to occupy the central part of the line, and also a station at a low level; the eminent French physicist, M. Janssen, taking up his position at the top of the Nielgherries. We were to station ourselves either east or west, or both, of these parties. Whether east or west would depend upon the monsoon, and the great question that was being discussed on our arrival was, Was the monsoon favourable?

I have not time to go into the many interesting points touching the answer to this question; but I may say shortly that what we heard was, that if the weather was likely to be bad on the east side of the hill range, generally called the Ghauts, there was a good chance for anyone occupying a position west of those hills. What happened was that we did occupy the positions marked by blue wafers on the map, viz., Bekul on the west coast, Manantoddy on the western

slope of the Ghauts, Poodocottah in the eastern plain, and in the Island of Ceylon—first, Jaffna, and secondly, Trincomalee.

Such were our arrangements. The parties were stationed along the line of totality. Very different were the arrangements of the Sicilian party of the former year. In Sicily we were compelled to throw ourselves across the line of totality in the direction which I have indicated on this map of Sicily.

Now what was the work we had to do? If you will allow me to refer to two or three results of the former eclipse Expedition, I will endeavour to put them before you without taking up too much of your time.

One of the most important among the results obtained in the eclipse of 1870 was this:—Far above the hydrogen which we can see every day without an eclipse—far above the prominences, the spectrum of hydrogen had without doubt been observed by two or three of the American observers, who were more fortunate than we were. Among them, Professor Young stated that the spectrum of hydrogen was observed to a distance of 8 minutes from the sun; he then adds, "far above any possible hydrogen atmosphere." This is point number one.

Another of the points was this: the unknown substance which gives us a line coincident, according to Young, with a line numbered 1474 by Kirchhoff, has been observed by the American observers to a height of 20 minutes above the limb of the dark moon.

Now, it was a very obvious consideration that, if we got a spectrum of hydrogen 8 minutes from the dark moon, when we thought we knew that the hydrogen at the sun did not really extend more than 10 seconds beyond the dark moon, there was something at work which had the effect of making it appear very much more extensive than it really was; and it was fair to assume that, if this happened in the case of the hydrogen, it might also happen in the case of the unknown stuff which gives us the line 1474.

In support of this view we had one of the few observations which were made in Sicily, in the shape of a drawing of the corona, as seen by Professor Watson, who observed at Carlentini. He saw the corona magnificently; and being furnished with a powerful telescope, he made a most elaborate drawing of it, a rough copy of which I will throw on the screen. You will see at once that we had in this drawing something which seemed to militate against the idea that the 1474 stuff at the sun did exist to a height of 20 minutes. According to Professor Watson, the boundary of the real corona was clearly defined, its height being far under that stated.

Next, we had another observation of most important bearing on our knowledge of the base of the corona. I refer to the announcement of the observation by Professor Young of a stratum in which all the Fraunhofer lines were reversed. It was asserted that there was undoubtedly a region some 2 seconds high all round the sun, which reversed for us all the lines which are visible in the solar spectrum. We had, in fact, in a region close to the photosphere, the atmosphere of the sun demanded by Kirchhoff at some distance above the photosphere.

Last, not least, we had the photographic evidence. There was in Sicily a photographic station at Syracuse, and the Americans had another in Spain. I now show on the screen a drawing—it is not the photograph itself, but a drawing of a photograph made by the party in Sicily; what we have on this photograph is a bright region round the dark moon, which is undoubtedly solar, but stretching out right away from this, here and there, are large masses of faint light with dark spaces between them, which have been called rifts. Now the question is, Is this outer portion solar?

Having thus brought rapidly before you some of the questions which we had principally to bear in mind, and, if possible, settle (though that is too much to hope for in any one Eclipse Expedition) in the work we had to do in India, I will next bring to your notice some new methods

* A Lecture delivered before the Royal Institution of Great Britain. The chief results obtained by the expedition have been taken from the *ad interim* Report presented to the British Association Meeting at Brighton. The lecture itself dealt mainly with the methods and instruments employed.—J. N. L.

of inquiry which had been proposed with the object of extending former observations.

I may here remark that the Royal Astronomical Society, in the first instance, invited me to take charge of an expedition to India merely to conduct spectroscopic observations; but, although this request did me infinite honour, I declined it, because the spectroscope alone, as it had been used before, was, in my opinion, not competent to deal with all the questions then under discussion. I have told you that some of the most eminent American observers had come to the conclusion that the spectrum of hydrogen observed in the last eclipse round the sun, to a height of 8 minutes, was a spectrum of hydrogen "far above any possible hydrogen" at the sun. Hence it was in some way reflected. Now, with our ordinary spectroscopic methods, it was extremely difficult, and one might say impossible, to determine whether the light which the spectroscope analysed was really reflected or not; and that was the whole question.

It became necessary, therefore, in order to give any approach to hopefulness, to proceed in a somewhat different way in the 1871 expedition, and, in order to guard against failure, to supplement such new observations by photographs; and fortunately we were not long in coming to a conclusion that this might be done with some considerable chance of success.

I have here a train of prisms. I will for one moment take one prism out of the train, and we will consider what will happen if we illuminate the slit of the lantern with a monochromatic light, and observe it through the prism. If we render sodium vapour incandescent, we know we get a bright yellow image of the slit, due to the vapour of the metallic sodium only giving us yellow light. But why is it that we get a line? Because we always employ a line for the slit. But suppose we vary the enquiry. If, instead of a straight line, we have a crooked line for the slit, then we ought to see a crooked line through the prism. Now allow me to go one step further. Suppose that, instead of a line, whether straight or crooked, we have a slit in the shape of a ring, shall we see a ring through the prism? You will see that we shall. And then comes this question: If, when we work in the laboratory, we examine these various slits, illuminated by these various vapours, why should it not happen that, if we observe the corona in the same way, we shall also get a ring built up by each ray of light which the corona gives to us; since we know, from the American observations, that there were bright lines in the spectrum of the corona, as observed by a line slit? In other words, the corona examined by means of a long train of prisms should give us an image of itself painted by each ray which the corona is competent to radiate towards us.

Now let us pass to the screen, the screen merely replacing the retina. We will first begin with the straight slit, with which you are familiar—we now have our slit fairly focussed on the screen—we then in the path of the beam interpose one of these prisms, and there we get on the screen a bright line.

Now, to continue the argument, we replace the straight slit by a crooked one, and you see we get a crooked image on the screen. We now replace this crooked slit by a ring. We have now a ring-formed image on the screen. So that you see we can use any kind of narrow aperture we choose, and as long as we are dealing with light which is monochromatic, or nearly so, we get an image of the aperture on the screen.

If we consider the matter further, it will be evident that we may employ a mixture of vapours, and extend this result.

We will now, for instance, instead of employing sodium vapour, employ a mixture of various vapours. You see now that each ray given by these substances, instead of building up a line image, is building up for us a ring image—that we have now red, green, yellow, blue, and violet rings.

Now that was the consideration which led to the adoption of one of the new attempts to investigate the nature

of the corona used this time. It was, to use a train of prisms, pure and simple, using the corona as the slit, a large number of prisms being necessary to separate the various rings we hoped to see, by reason of their strong dispersion. On the screen the rings to a certain extent intersect each other; and it would have been easier to show you the ring-form of the images if we could have used more prisms than one.

If this is good for a train of prisms such as I have referred to, it is good for a single prism in front of the object-glass of a telescope. Such was the method adopted by Prof. Respighi, the distinguished Director of the Observatory of the Capitol of Rome, who accompanied the expedition.

Now you may ask, How would this method, if it succeeded, be superior to the ordinary one. In this way. If we were dealing merely with reflexion, then all the rings formed by vapours of equal brilliancy at the base of the chromosphere would be of the same height, while if reflexion were not at work the rings would vary according to the actual height of the vapours in the sun's atmosphere, and the question would be still further advanced if the spectrum did not contain a ring representing the substance which underlies the hydrogen.

Our new spectroscopic equipment, then, was as follows:—

1. A train of five prisms.
2. A large prism of small angle placed before the object-glass of a telescope.
3. Integrating spectroscopes driven by clockwork.
4. A self-registering integrating spectroscope, furnished with telescopes and collimators of large aperture, and large prisms. (This instrument was lent by Lord Lindsay.)

Now a word about the polariscopic instruments, referring you to my lecture given last year for a general notion of the basis of this class of observation.

A new idea was, that observations to determine the polarisation of the corona might be made with the same telescope and eye, both with the Biquartz and the Savart.

By the kindness of Mr. Spottiswoode, who has placed his magnificent polarising apparatus at our service, I hope to be able to show you on the screen the mode of examining the corona by means of those two instruments, so as to enable you pretty well to follow what was actually done.

Let me begin with the Biquartz polariscope. In the first instance I will throw on the screen a representation of the corona itself, and we will then insert a Biquartz, and see its effect when I flood the screen with polarised light. You now see an indication of what would be observed supposing the polarisation was due to polarised light diffused in the region between us and the dark moon and eclipsed sun, in which case the polariscopic effect would be observed generally over the dark moon, the corona, and the region of the sky outside the corona. But this is not all; not only does this arrangement enable us to determine the existence of such a general polarisation, but the vertical line in the Biquartz called the line of junction indicates the plane of polarisation, when the colours on both sides of it are the same; so that we have two colours strongly contrasted in either half of the field when we are away from the plane of polarisation, and a uniform colouring of the whole field when in or at right angles to that plane. By turning this prism through 90 degrees, you see I entirely change the colours.

But we are not limited to the Biquartz in this inquiry. We can apply the Savart polariscope. Having still our image of the corona on the screen, I now replace the Biquartz by a Savart.

We now no longer see a line of junction with the similar or different colours on either side of it, but lines of colour running across the image. I turn the prism. We first see the lines with a white centre, then with a dark one, while at times they are altogether absent. And as a departure from the plane, when we use the Biquartz, gives us the strongest contrasts of colour, so you observe that

with the Savart under these circumstances all indications of polarisation vanish.

Now, if we assume polarisation to be general, and the plane of polarisation vertical, we should get those coloured bands, as you see them there, crossing the corona and dark moon, the lines being vertical and dark-centred. If the plane of polarisation were horizontal, we should find the lines horizontal and the central one white.

But so far as we have gone we have been dealing with polarisation which is general, and we have not attempted to localise polarisation at the corona itself. But I have here an apparatus, by means of which, quietly, in this theatre, one can see as admirable an example as we should desire of polarisation, assumed to be particular to the sun and not general—I mean radial polarisation. We have simply a circular piece of mahogany, or something else which polarises light equally well, with a hole in the middle with sloping sides, cut as you see this cut, and then we place behind it a candle, so that the light of this candle, after falling on oiled tissue paper stretched across the aperture, can be reflected to the eye by the sides, the direct light of the candle being stopped by a central metallic diaphragm. We have now a source of polarised light of a different kind from the last. The next thing we have to do is to introduce into a small telescope exactly the same kind of apparatus we have there, though of course on a much smaller scale, and examine the ring of light seen when we put the candle behind the aperture. On examining the ring of light which is now visible by means of this telescope, which contains a Biquartz and analyser, I see the most exquisite gradations of colour on either side the line of junction which cuts the field of view and the bright ring in the centre into two.

Now, instead of the candle, we will employ the electric lamp; and instead of the eye, the screen; but I must inform you that the great heat of the electric lamp prevents the appearance being perfectly successful on the screen, as the reflecting varnish is melted.

In this experiment we cannot work with an image of the corona. We must make our corona out of the image of the ring we hope to get on the screen, and then, by employing the Biquartz in the same way as before, instead of getting similar colours on either side of the line of junction, as we did when we were working in the plane of polarisation, and getting the greatest contrasts, as we did when we worked 45 degrees away, you observe we get different colours in each part of the ring.

On the screen we now have a highly-magnified image of the hollow cone of iron which I am compelling to reflect the light from the lamp; and by inserting this Biquartz I throw various colours over different portions of that ring, which I beg you to consider for one moment as the solar corona, and the colours change as I rotate this prism. You will at once be able to explain the different actions of this Biquartz in this instance. The reflexion, and therefore the plane of polarisation, is no longer general, but varies from point to point of the reflecting surface. It is in fact radial, and hence the delicate radiate arrangement of colour.

Such, then, were some of the new methods and new instruments we used, for the first time, in our researches.

(To be continued.)

NOTICES OF BOOKS.

Investigation of some of the Ammoniacal Waters of Gas-Works, and on the Presence of Chlorine Compounds in Coals. By Dr. G. TH. GERLACH.

This essay contains in detail the method of analysis and the results of the author's researches on several kinds of ammoniacal liquor, as obtained from various kinds of coal at some of the German gas-works. As instances, we quote

the following:—100 c.c. of the ammoniacal liquor of the Chemnitz (Saxony) gas-works, where Zwickau coal is used, contain, in grms.—Hyposulphite of ammonia, 0.1036; sulphuret of ammonium, 0.0340; bicarbonate of ammonia, 0.1050; carbonate of ammonia, 0.4560; sulphate of ammonia, 0.0462; sal-ammoniac, 3.0495. Gas-water from the Bonn gas-works, where Rahr coals are used, contains, in 100 c.c., in grms.—Hyposulphite of ammonia, 0.5032; sulphuret of ammonium, 0.6222; bicarbonate of ammonia, 0.245; carbonate of ammonia, 3.3120; sulphate of ammonia, 0.1320; chloride of ammonium, 0.3745. The author calls special attention to the fact that the presence of chlorine compounds in coals has been hitherto overlooked, because these compounds are volatilised in the shape of chloride of ammonium when the coal is incinerated. The quantity of chloride of sodium in the Zwickau coal amounts to about 3 per mille, and, since it contains about 2 per cent of ash, that ash should contain about 15 per cent of chloride of sodium.

Das Anthracen und Seine Derivate. Für Technik und Wissenschaft nach der bis jetzt bekannten Quellen Zusammengestellt. Von G. AUERBACH, Assistent am Eidgenössischen Polytechnicum zu Zürich. Berlin: O. Seeheagen. 1873.

THIS work is scientifically and industrially of great value. We quote the headings of the leading chapters:—Introduction, containing historico-scientific review of the discovery of anthracen in 1832 by Dumas and Laurent, who called it paranaphthalin, and a *resumé* of the researches of a large number of *savants* up to the present day; constitution of anthracen and its derivatives; preparation and properties of anthracen; hydrides of anthracen; bromine derivatives of anthracen; chlorine and anthracen; nitro- and sulpho-compounds of anthracen; azo combinations of anthrachinon; other combinations of anthrachinon; alizarine (this chapter contains valuable information on the researches on madder, its preparations, its colouring principles, and its chemical combinations); chrysophanic acid; chrysammic acid; franguline; frangulinic acid; an appendix, containing practical receipts for dyeing with native and artificially-prepared alizarine. The author is to be congratulated for the clear and excellent manner in which he has treated his subject. In addition to a general index, we notice a plan which might be more generally adopted, under the title of "Autoren register," an alphabetically-arranged index; for instance, under Alizarine we find a complete list of, not only the names of authors, but the periodicals in which their essays are published. The numerous and complex formulæ are prominently set forth.

CORRESPONDENCE.

SANITARY ARRANGEMENTS OF THE METROPOLIS.

To the Editor of the Chemical News.

SIR,—I beg most respectfully to submit the following for the favour of your consideration; my apology for doing so being that it is a sanitary question of considerable importance, not merely to the inhabitants here in particular, but to the public generally. Our Medical Officer of Health states that there are 100 fish-smoking houses in this parish. One of these is in the heart of a densely populated neighbourhood. In it are cured—according to the report of our own Medical Officer of Health—every night, including Sundays, between 40,000 and 50,000 herrings. Fourteen fires, made from the roots of oak and hornbeam, are burning therein at one time, the fumes of which roll out in volumes filling our houses with noxious

gases, even when our doors and windows are shut. The louver boards from which the effluvia escape are at the same elevation as our bedroom windows, and there is no chimney-shaft to carry the effluvia away from our abodes.

Four physicians, viz.—Dr. Godfrey, 33, Finsbury Square; Dr. Bate, 412, Bethnal Green Road; Dr. Tripe, 172, Richmond Road, Hackney; and Dr. Simpson, 233, Hackney Road—have certified the smoke-house a public nuisance, and greatly injurious to health. Numbers of chemists in this neighbourhood have affirmed the same thing. The Vestry—men who know no more of chemistry than a codfish—having been applied to repeatedly by the inhabitants, have not only persistently refused to abate or remove the pest, but have always avowed themselves the defenders and patrons of it. We have also petitioned the Local Government Board, but they declare themselves powerless to do anything except to endorse the decision of the Vestry. Therefore our health is being wantonly destroyed without remedy, because this is too poor a neighbourhood for us to be able to bear the legal expenses necessary to suppress the nuisance which was brought to us, for we did not come to it, and our removing from it would in many cases involve the breaking up of our homes, and the ruin of our business, with the chance of some other nuisance equally pernicious being brought to us in whatever other place we might remove to. If this is Vestry and Local Government Board management, of what use is either of them? So far as our health is concerned we could not be worse off under Turkish despotism.—I am, &c.,

R. M. GURNELL.

17, Peel Grove, Old Ford Road, Bethnal Green,
October 29, 1872.

A MODIFICATION OF MOHR'S BURETTE.

To the Editor of the Chemical News.

SIR,—In reference to the letter of Mr. Edward Collens in your Paper of the 24th inst., in which he claims to have adopted the modification of Mohr's burette which was published in your previous number, we beg to say that having referred to his paper we at once admit the justice of his claim, and regret that we were not aware of it when we sent our description of what we believed to be quite new.

We are still of opinion that our plan in its details will be found the more convenient of the two, as it neither involves the long glass tube (with its great liability to fracture), nor any material alteration of the burette; but, nevertheless, the utmost we can claim is to have improved the arrangement.

Having said this, we feel the more at liberty to express our surprise at the objections urged against this plan, as in practice we find it nearly perfect. The leakage is absolutely *nil* in moderate sized burettes. The air bubble is less than in the ordinary arrangement, and the difficulty in regulating the flow from a large orifice can be effectually overcome by applying a screw pinch-cock in addition to the ordinary one.—We are, &c.,

M. HERIOT,
R. BIGGS.

A MODIFICATION OF MOHR'S BURETTE.

To the Editor of the Chemical News.

SIR,—Permit me to reply to your correspondent, who recites his experience on the above subject as gained in Messrs. Vernon Harcourt and Esson's investigations.

His first charge, which relates to the changes of temperature influencing the readings, is perfectly correct, but the error from this source is not such as to condemn the burette. The temperature of a laboratory is not, as a rule, subject to violent fluctuation; nor, at least in the majority of cases, is it necessary, when using a burette, to preserve the same reading hour after hour.

His second objection, viz., the difficulty experienced in delivering single drops by this arrangement, can be completely overcome by substituting a screw-clamp for the ordinary pinch-cock—such things are to be obtained of the apparatus dealers; and by its use a whole buretteful of fluid may, with the greatest ease, be delivered drop by drop, either fast or slow, without the clumsy suggestion of your correspondent's, which would defeat its own end by causing the instrument to drop after the supply of air had been cut off.

It is hardly necessary to reply to his third objection. A chemist who cannot fit a cork into a half-inch tube, and pass another and much smaller tube through it sufficiently tight to sustain a pressure of, say, 1 lb. on the square inch, is scarcely an authority on manipulation.

I quite agree with his remarks upon the superiority of the glass stop-cock modification, but every laboratory is not fitted with these. The real use of the modification in question is the ready means it affords chemists of converting their Mohr's burettes in a few minutes into instruments capable of being used with any test-liquors, an advantage which might have been disregarded had your correspondent's remarks not been replied to.—I am, &c.,

EDWARD COLLENS.

Birmingham Vinegar Brewery,
October 28, 1872.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, October 28, 1872.

This number contains the following original papers and memoirs more particularly relating to chemistry:—

Researches on Fermentation.—E. Frey.—A reply to a question by Pasteur. An animated debate followed the reading of the paper at the meeting.

Researches on Crystalline Dissociation; Alums.—P. A. Favre and C. A. Valsen.—The continuation of an exhaustive essay on this subject, elucidated by a series of tables.

New Studies on Valerianic Acid and its Preparation on the Large Scale.—I. Pierre and E. Puchot.—Valerianic acid, obtained by the oxidation of amylic alcohol, and concentrated as much as possible, boils at 178°, and has at 0° a sp. gr. = 0.947, and at 147.5° = 0.8095; the acid contains 1 equivalent of water, which cannot be eliminated by distillation. When in the presence of an excess of water, it boils at between 99.8° and 100°, forming vapours, which, by their condensation, yield two distinct layers of liquid; the lower layer is an aqueous solution of the acid, and the upper one is a hydrate of the acid; the proportion of these layers to each other is as 23 to 77. Valerianic acid causes the plane of polarisation to deviate in the same direction as crystallised sugar, while amylic alcohol does the reverse.

New Studies on Butyric Acid.—I. Pierre and E. Puchot.—Butyric acid, obtained by the oxidation of butyric alcohol, boils at 155.5° when quite concentrated, and has at 0° a sp. gr. = 0.9697, and at 139° = 0.822; this acid does not act upon polarised light. The formula of dry butyrate of baryta is $C_4H_7O_2BaO$. Ethylic butyrate boils at 113°, and has at 0° a sp. gr. = 0.89, and at 100° = 0.779. Methyl butyrate boils at 93°, and has at 0° a sp. gr. = 0.9055.

Note on the Purple of Cassius.—H. Debray.—Reserved for full translation.

Smelting of Platinum.—H. Violette.—The author describes a small blast-furnace constructed by him at a chemical work at Lille, and communicating with the factory chimney; by the aid of this furnace the author states that he has been able to smelt 50 grms. of platinum placed in a crucible made of graphite placed in a fire-clay crucible. The heat generated is, according to the author, exceedingly great, although the cubical capacity of the furnace is only 45 litres. Coke was first used as fuel, but the author has found it better to use the graphite, as it does not contain ash. There is added to this paper a footnote by the Perpetual Secretary of the Academy, who asks

whether it is not possible that the platinum may have taken up a trace of carbon, silicon, or sulphur, whereby its fusion-point is lowered.

Chemical Researches on the Leaves of the Eucalyptus Globulus.—Dr. Rabuteau.—The author states that these leaves contain no alkaloid.

Researches on the Physiological Theory of the Alcoholic Fermentation set up by Beer Yeast.—A. Béchamp.—The contents of this monograph are not suited for abstraction.

Annales de Chimie et de Physique, November, 1872.

This number contains the following original papers and memoirs:—**Simple Reactions Limited by Inverse Action; Application to the Conversion of the Phosphorus.**—G. Lemoine.—The first portion of an exhaustive monograph, elucidated by algebraical and chemical formulæ and tabulated forms, and divided into the following sections:—Non-limited simple reactions; dissociation, homogeneous system; dissociation, non-homogeneous system; allotropic conversion of phosphorus.

Researches on Aromatic Combinations.—Dr. A. Wurtz.—The second instalment of this memoir contains the following chapters:—Synthesis of aromatic acids; synthesis of benzoic and toluic acids; dibenzyl-carboxylic acid; salts of this acid.

New Locality for Amblygonite; and on Montebrazite, a New Phosphate of Alumina and Hydrate of Lithia.—M. Des Cloizeaux.—This essay, illustrated by woodcuts, is in substance the same as that already quoted from the *Comptes Rendus* (see *CHEMICAL NEWS*, vol. xxiv., p. 97).

Silicic Mercaptan and a Chlorobromide of Silicon.—C. Friedel and A. Ladenburg.—After referring to the researches of I. Pierre on chlorosulphuretted silicon, the authors state that they prepared a larger quantity of that substance, care being taken to render it pure; on continuing their researches they found that the compound discovered by M. Pierre is a chlorosulphhydrate of silicon which may be viewed as a tetrachloride of hydrosulphuric acid; this body is a limpid colourless liquid, which boils at 96°, exhibits the odour of sulphuretted hydrogen and hydrochloric acid, and is decomposed by exposure to air, the two volatile acids escaping, and silica being deposited. Absolute alcohol decomposes this compound at the ordinary temperature, hydrochloric acid being set free; the formula of this compound is SiCl_3SH . The chlorobromide of silicon, SiCl_2Br , is a colourless liquid, decomposed by the addition of water into silica and chlorhydric and bromhydric acids; boiling-point, 80°; vapour density, 7.25 (theoretically 7.42). The chlorosulphhydrate of silicon may be considered as analogous to the methylic mercaptan, CH_3SH .

Mixed Silico-Acetic Anhydride.—C. Friedel and A. Ladenburg.—After first referring to the labours of Gerhardt, Kaemmerer, Carius, Menschutkin, and others, on mixed mono- and poly-basic anhydrides, the authors describe the preparation of this compound by the reaction of chloride of silicon upon acetic or anhydrous acids; this reaction is elucidated by the following formulæ:—

The silico-acetic anhydride is a white crystalline body, very hygroscopic, and decomposed by water; under reduced pressure it may be distilled without decomposition; it fuses at 110°, and boils at ordinary atmospheric pressure at 170°, but is then decomposed. The formula of this body is $\text{Si}(\text{C}_2\text{H}_3\text{O}_2)_4$; alcohol decomposes this substance, with formation of acetic ether and deposition of silica.

Bulletin de la Société Chimique de Paris, September 1 and 15, 1872.

This number contains the following original papers and memoirs:—**Compounds of Yttrium and Erbium.**—P. T. Clève and O. Hoeglund.—The first instalment of a monograph on this subject, divided into the following sections:—Introduction, containing a review of the labours of different savants on these metals, beginning with the discovery by Gadolin of yttria, in 1794, in a mineral named gadolinite; atomic weight of yttrium, estimated according to the method of Bahr and Bunsen, and found by the authors to be equal to 59.7 ($\text{O}=16$); atomic weight of erbium, equal to 137; oxide of yttrium; hydrate of yttrium; oxide of erbium; hydrate of erbium, $2(\text{ErH}_2\text{O}_2) + \text{H}_2\text{O}$; salts of yttrium; salts of erbium. This portion of the essay is elucidated by a large number of complex formulæ, and also contains the detailed description of a number of double salts of the metals.

Some Derivatives of Tetrachloride of Naphthalene.—E. Grimaux.—By heating, under pressure, pure tetrachloride, which fuses at from 179° to 180°, with water (30 parts to 1 of the tetrachloride) a compound is formed, which the author terms bichlorated naphthydrenic glycol, $\text{C}_{10}\text{H}_2\text{Cl}_2(\text{OH})_2$, a solid crystalline substance, difficultly soluble in cold water, more soluble in boiling water, and readily soluble in alcohol and ether. With chloride of acetyl, this body yields a diacetate, also a solid crystalline body—

soluble in alcohol and ether, and fusing at between 130° and 131°. With chloride of benzyl, the bichlorated naphthydrenic glycol yields a dibenzoate—

which, on being treated with alcoholic potassa solution, forms benzoic acid. When the bichlorated naphthydrenic glycol is distilled with hydrochloric acid, there is formed chlorated naphthol, $\text{C}_{10}\text{H}_2\text{Cl}_2\text{OH}$, a solid body, soluble in boiling water, and fusing at 109°; the formation

of this compound is explained by admitting that an intermediate compound chlorhydrine—

is first formed; this intermediate chlorhydrine has not been isolated. The author devotes a large portion of this essay to a theoretical discussion on the formation of the chlorated naphthol. Treated with strong boiling nitric acid, the bichlorated naphthydrenic glycol yields a nitro-compound; with dilute nitric acid, phthalic acid is formed. By treatment with nitrate of silver, tetrachloride of naphthalin yields a solid yellow-coloured body, $\text{C}_{10}\text{H}_2\text{Cl}_2\text{O}_2$, insoluble in water, fusing at from 195° to 196°.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, July 4, 1872.

Extraction of Grease from Bones.—Lichtenberger.—The bones are first crushed, next treated with high-pressure steam, and to the semi-gelatinous mass thus formed is added hydrochloric acid (2 per cent), with which the material is boiled; by this operation the fat is separated and, floating on the top of the boiling liquor, is readily collected, and further purified by treatment with boiling water, a very small quantity of caustic soda having been added. Next, the grease (a fluid oil-like substance) is treated with animal charcoal, and, lastly, filtered.

Remarkable Instance of Disaggregation of Metallic Tin.—Dr. Oudemans.—It appears that a quantity of Banca tin was sent last winter by rail from Rotterdam to Moscow; on its arrival the metal was all converted into a powder, which, on being submitted to heat (somewhat above the fusion-point of the metal), did not become molten and re-converted to its pristine state, owing to the formation of a large quantity of oxide. Analysis proved the powder to be pure tin containing only 0.3 per cent of foreign metals (lead and iron). The author is of opinion that the blocks of tin were converted into powder by the combined action of cold and vibration during the journey by rail.

Process of Titration of Defecated Beet-Root Juice.—V. Vivien.—The author describes a method of testing beet-root juice for the purpose of ascertaining whether or not the excess of lime employed in the process of defecation of the juice has been properly removed from that liquor by the means industrially applied for that purpose. The author recommends the use of pure sulphuric acid, of which he takes 8.75 grms. to the litre of water; this solution is tinged red with a neutral tincture of litmus, and next diluted with 9 times its bulk of pure water. This liquid neutralises exactly its own bulk of clear defecated beet-root juice, when containing 5-10,000ths of lime. In order to test the beet-root juice, it is poured into a graduated tube made for the purpose, and the dilute sulphuric acid is added from a graduated pipette until a bright red colour is produced; if it is necessary to add an equal bulk of acid, the juice then contains 1 grm. of lime to the litre (equal to 5-10,000ths), but, if only required for the production of the red hue to, say, the third graduation of the tube, the juice still contains 2-1000ths of lime.

Artificial Miniature Volcano.—Dr. Hochstetter.—After referring briefly to the well-known experiments of Lemery, the author states that when sulphur is molten under water by the aid of high pressure (3 atmospheres=45 lbs. to the square inch), the sulphur absorbs some water, which is next driven off when the sulphur cools down, and this emission of steam is accompanied by explosions and evolution of fumes, whereby in the sulphur, provided the quantity operated upon is sufficiently large (not less than 50 kilos.), an upheaving takes place, and formation of craters, as well as emission of molten sulphur, thus simulating lava.

Benzoic Acid in Ammoniacal Gas-Water.—H. Reidsch.—By first treating the gas-water at 50° with sulphate of lime, the carbonate of ammonia contained in that liquid is entirely decomposed, and there is obtained a solution of sulphate of ammonia strongly impregnated with tar compounds, which are separated with difficulty from the ammoniacal salts; but if the liquid is first evaporated at a gentle heat until all the water is expelled, and then further heated in a porcelain crucible covered with a small piece of mica, there is eliminated some benzoic acid in crystalline state, which adheres to the piece of mica.

Annalen der Chemie und Pharmacie, No. 11 and 12 (double number), 1872.

This number contains the following original papers and memoirs:—**Action of Sodium on Crystalline Dibrombenzol.**—Dr. F. Riese.—The results of a series of experiments to ascertain the nature of the compounds which are generated by the action of sodium upon dibrombenzol.

On β -Dibrombenzol.—Dr. F. Riese.—This body in pure state is a clear, mobile, and refrangible liquid, exhibiting an aromatic odour, soluble in cold alcohol, ether, and benzol in every proportion, and not congealed at -27° ; when converted into a mononitro-compound the author found that it is not identical with the dibrombenzol obtained by Kekulé, which fuses at 84°, while the former fuses at 58°, and distils over without alteration at 296°.

Observations on the so-called Anhydrides of Lactic Acid.—J. Wislicenus.—This exhaustive monograph, elucidated by complex formulæ and tables, is divided into the following sections:—Anhydriation (*anhydrißung*) of lactic acid at the ordinary temperature; anhydriation of lactic acid at higher temperatures; the salts of the so-called anhydride of lactic acid; decomposition of the so-called lactic

acid anhydride by water. The results of these researches may be summarised as follows:—Before all the water present in a solution of lactic acid has been evaporated, some anhydride is present in the solution, and the quantity of that anhydride increases as the water decreases; pure lactic acid (formula $C_3H_5O_3$) does not therefore exist. When lactic acid is continuously kept in a dry atmosphere there is formed, even at the ordinary temperature, an anhydride and also a lactide. The author thinks it is probable that the lactic acids form a chemical compound with water in the same manner as acetic, formic, and valeric acids, which form trihydrates corresponding to the formula:—

and have a higher boiling-point than the monohydrates—

which, however, become partly decomposed by distillation, while water is eliminated (*abgespalten*).

On Bichloro-Ether.—Dr. H. Abeljan.—This monograph is chiefly written to correct the labours of Lieben; it contains a large number of complex formulæ, and is divided into the following sections:—Introduction, treating on the preparation of the bichloro-ether, and on the products obtained by the action of dry hydrochloric acid gas upon aldehyde, and by the action of dry chlorine upon ethyl-ether; action of pentachloride of phosphorus upon bichloro-ether; decomposition of bichloro-ether; decomposition of bichloro-ether by alkali; general review of the results exhibited in a large number of lengthy and complex formulæ.

On Diphtalyl.—Dr. E. Ador.—This exhaustive essay treats on the preparation of diphtalyl by causing finely-divided metallic silver to act upon phthalyl chloride; the purified diphtalyl is a solid crystalline body, quite insoluble in water, scarcely soluble in alcohol and ether, but somewhat soluble in chloroform, sulphide of carbon, and fluid hydrocarbons; the best solvents for it are phenol and concentrated sulphuric acid; it fuses at 300° ; its simplest formula is $C_{12}H_8O_2$. Action of alkalies upon diphtalyl; diphtalyl-aldehydic acid; diphtalyl acid; salts of this acid; capability of oxidation of diphtalyl acid; behaviour of diphtalyl-aldehydic acid and of diphtalyl acid in a higher temperature; action of pentachloride of phosphorus and of bromine upon diphtalyl; by-products of its preparation.

Some of the Cyanogen Derivatives of Aceton.—Dr. F. Urech.—It appears that the author, who briefly alludes to the labours of Morkownikoff, Städeler, Dr. Frankland, Duppa, and others on this subject, was desirous of preparing trimethylen-dicarboxylic and dimethyl-malonic acids, starting from acetic acid, first to be converted into α -brom-isobutyric acid. The monograph is divided into the following sections, all copiously elucidated by lengthy and complicated formulæ:—Action of anhydrous hydrocyanic acid, of nascent hydrocyanic acid, of cyanide of potassium, of cyanate of potassa, and of hydrochloric acid upon aceton; acetonyl-urea; splitting up of acetonyl-urea by acids; α -amido-isobutyric acid; hydrochloro- α -amido-isobutyric acid; synthesis of acetonyl-urea from its products of splitting up (*spaltungsproducten*) by the aid of acetonyl-uraminic acid; general review exhibited in a large number of formulæ.

Constitution of Sodium Ethylate.—A. Laubenheimer.—This paper treats more particularly on the constitutional formula of sodium ethylate, and the author states that, although otherwise agreeing with the excellent researches of Professor Wanklyn on this subject, the formula of sodium ethylate should be C_2H_5ONa instead of $C_2H_5Na.OH$.

Behaviour of Milk-Sugar with Permanganate of Potassa.—A. Laubenheimer.—The researches recorded in this essay were made partly to try whether it would be possible to obtain isomalic acid from milk-sugar, and partly to ascertain whether lactose is or is not completely oxidised, when in alkaline solution, by permanganate of potassa, it being premised that 1 molecule of milk-sugar requires for complete oxidation 24 atoms of oxygen—

The result of a series of experiments shows that lactose is slowly, but nearly completely, oxidised at the ordinary temperature, and rapidly at boiling heat of the solution, being entirely converted into carbonic acid and water. The formation of isomalic or malic acids from sugar of milk was not observed, but the author obtained carbonic and oxalic acids and an acid which, although not obtained in sufficiently pure state for analysis, appears to be akin to gallacetic and petcolactonic acids, the formulæ of which are, respectively, $2HO.C_{14}H_{14}O_7$ and $2HO.C_{16}H_{16}O_{10}$.

Presence of Benzyl Alcohol in Fluid Storax.—A. Laubenheimer.—After briefly referring to the researches made on storax by Bonastre, E. Simon, E. Kopp, Toel, Scharling, and others, and stating that storax, in addition to resins, contains styrol, C_8H_8 , cinnamic acid, $C_9H_7O_2$, styracine (cinnamic acid-cinnamin ether), $C_9H_7(C_6H_5)O_2$, the author details some researches made with a preparation obtained by the saponification of impure styracine, and kept in the collection of chemical preparations of the University of Giessen. Among the products of a careful fractional distillation the author found a small quantity of benzyl alcohol, and also an alcohol, $C_9H_{10}O$, boiling at 243° , and cuminal alcohol, $C_{10}H_{14}O$.

Ethyl Ethers of Fumaric Acid.—A. Laubenheimer.—It appears that, when fumaric acid is heated with absolute alcohol under pressure to 120° , an ethylic ether of that acid is readily formed; this substance

is in pure state a solid body, which, on analysis, was found to be the acid ether of the acid, or ethyl-fumaric acid—

This mode of its preparation is, however, attended with loss of material, and the author prefers to prepare it by passing hydrochloric acid gas into a boiling alcoholic solution of malic acid, but in that case the purification of the ether becomes rather a complicated affair.

Reduction-Products of Sililic Acid Ether, and on some of its Derivatives.—A. Ladenburg.—This exhaustive monograph is divided into the following sections:—General introduction and review of the labours of other savants; silicium-monetil or silico-propion series; silicium-diethyl series; silicium-triethyl or silico-heptyl series; silicium-tetra ethyl series.

Nonylic Acid from the Octyl Alcohol of Heracleum Oil.—Th. Zincke and A. Franchimont.—After referring to their researches on heracleum oil and the alcohols therein contained, observing that the octyl alcohol present in the oil has also lately been discovered by Dr. L. van Renesse in the essential oil obtained from *Pasinaca sativa*, the authors treat on nonylic acid, $C_9H_{18}O_2$, in pure state a colourless oily fluid, boiling at 254° , sp. gr. at $17.5^\circ = 0.9065$, difficultly soluble in cold water, but slowly distilled over with the vapours of boiling water; at a low temperature nonylic acid becomes solidified, and then melts at 10° . The preparation of this acid from the octyl alcohol is given in detail, as is also the description of the salts which this acid forms with bases; the constitution of this acid is discussed at length, and there is added to that portion of the essay a tabulated form exhibiting the boiling-points of a series of acids belonging to the same series of bodies, and of their ethylic ethers.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, November, 1872.

This number contains no original papers relating to chemistry; we call attention, however, to the following memoirs:—

Report on a Modérateur Aspirateur Hygénique to be Applied to Stoves and Heating Apparatus, and Invented by M. Henry.—H. Peligot.—The description, illustrated by engravings, of a simple and effective contrivance for carrying off the foul air from rooms where stoves are used, without creating a draught; the unpleasant odours of cooking operations are also discharged into the chimney.

Experiments made with Leadon Balls Discharged from Rifles.—Melsens.—A valuable contribution to ballistics and the effects of leadon balls upon stone, brick, iron, soft substances, &c.

Preservation of Eggs.—A. Gaffard.—The fresh eggs are carefully placed in a mixture of 5 kilos. of alum dissolved in 5 litres of water, heated to from 45° to 50° , and left in that liquid for from thirty to forty minutes; the eggs are next drained, and in the meantime the solution of alum is heated to boiling-point. The eggs are again immersed in the liquid, and kept therein for from ten to fifteen seconds; after having been drained and cooled they are packed in either dry bran, sawdust, cork-dust, sifted ashes, or in cotton-wool, and may be kept fresh for a whole year.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 15, 1872.

This number contains the following original papers and memoirs:—

Coerulignon, a By-Product of the Manufacture of Wood-Vinegar.—C. Liebermann.—The substance designated as coerulignon is so called owing to its blue colour; it has recently been discovered during the process of purification of the crude wood-vinegar or pyroligneous acid in the factory of Th. Lettenmayer, near Königsbrunn (Prussia). We intend to give a full translation of this paper.

Oxidation of Camphor Cymol in the Animal Body.—M. Nencki and E. Ziegler.—This paper records the results of experiments made upon dogs and men by administering doses of cymol prepared from camphor. The authors found in the urine, by a complicated process of purification, terephthalic acid and cuminic acid, being similar to the products of the artificial oxidation of these substances by chromic acid.

Products of Reduction of the Orthoformic Ether.—A. Ladenburg.—The result of the reduction of orthoformic ether by means of zinc-ethyl and sodium is, after a complicated process of operation, probably propional and a heptyl hydruet, $CH(C_2H_5)_3$, which the author calls triethyl-methan, a colourless liquid, exhibiting an odour somewhat like petroleum, boiling at 96° ; sp. gr. at $27^\circ = 0.689$.

Application of Electrolysis to the Estimation of the Molecular Weight of Substances.—A. Ladenburg.—The contents of this paper are written to correct the views of Paterno (see CHEMICAL NEWS, vol. xxvi., p. 71).

Influence of Caoutchouc Tubing upon the Illuminating Power of Coal-Gas.—K. Zulkowsky.—The main results of the investigation may be summarised as follows:—(1). When it is intended to estimate the illuminating power of coal-gas, the gas should not be made to pass, before reaching the test-burners, through india-rubber tubing. (2). The decrease of the illuminating power is due to the absorption of the heavy hydrocarbons by the tubing material. (3). This behaviour of caoutchouc should be borne in mind when analyses of coal-gas and similar gas mixtures are to be made.

Constitution of Camphoric Acid.—F. Wreden.—A preliminary notice. The author first refers to the researches of Chapman, Thorpe, Fittig, Baeyer, and others, and then states that, according to his

investigation, camphoric acid is a corresponding dimethyl-benzol homologue of Baeyer's hexahydrophthalic acid.

Contribution to the History of Bromide of Vinyl.—E. Fuchs.—Notwithstanding the high scientific value of this essay, its contents, elucidated by complex and lengthy formulæ, are not well suited for abstraction; an observation equally applicable to the following lengthy monograph:—

Affinity of Hydrogen to the Metalloids.—J. Thomsen.

(Meta-)Chlorphenol and its Nitro-Derivatives.—A. Faust and H. Müller.—The preparation of monochlorphenol, by passing into pure molten phenol, is first described, and next the purification of the crude product. The pure monochlorphenol is a colourless oily fluid, not congealed below -15° , boiling at between 175° and 177° . It yields with nitric acid two isomeric mononitrochlorphenols; one of these—

is partly an oily, partly a crystalline, body, fusing at 70° , difficultly soluble in water, but readily so in chloroform; it exhibits an odour like that of saffron, and forms crystalline salts with several bases; the other nitro-compound, $\text{C}_6\text{H}_3[\text{NO}_2]\text{ClO}$, is a solid crystalline body, fusing at 110° to 111° ; it is identical with a chloronitrophenol obtained by Armstrong (*Journal of the Chemical Society*, x., 12, and *Zeitschrift für Chemie*, 1871, 591), and forms crystalline salts with several bases.

Chemical Processes which Obtain in Plants.—A. Emmerling.—Reserved for full translation.

Heptylic Acid from the Hexyl Alcohol of Heracleum Oil.—A. Franchimont.—After referring to some of his other researches on this subject, the author describes at length heptylic acid and several of its salts. The former is, at ordinary temperature, a colourless oily fluid, boiling at 223° to 224° ; it solidifies at -18° , forming a crystalline mass, which becomes fluid at -8° ; sp. gr. at 24° = 0.9212. Ethylic ether, prepared from the acid, absolute alcohol, and concentrated sulphuric acid, $\text{C}_{11}\text{H}_{21}[\text{C}_2\text{H}_5]\text{O}_2$; sp. gr. at 24° = 0.874; it boils at 187° to 189° , and is not solidified at -18° . Many of the salts of the heptylic acid are soluble only in strong alcohol.

Pentachlorbenzols.—A. Ladenburg.—This paper records a series of investigations for the purpose of controlling the statements by Jungfleisch and Otto. It appears that while the formulæ of both authors agree, there is a discrepancy as regards the boiling-points, and it would seem that there exists only one real pentachlorbenzol.

Dinitrobenzyl and Phenylhydrazine.—Th. Zincke and F. Sinteris.—This paper is not well suited for abstraction.

Some Derivatives of Diphenylmethane.—W. H. Doer.—Diphenylmethane, prepared by the action of finely-divided zinc upon benzyl chloride and benzol at boiling heat, is a crystalline body, exhibiting the smell of oranges, and fusing at 26° ; it has been applied by the author for the preparation of—Dinitro-diphenylmethane—

a solid crystalline body, fusing at 183° ; isodinitro-diphenylmethane, $\text{C}_{12}\text{H}_{10}(\text{NO}_2)_2$, also a crystalline body, insoluble in water, soluble in alcohol, ether, benzol, and acetic acid (glacial), fusing at 172° ; tetra-nitro-diphenylmethane, $\text{C}_{12}\text{H}_6(\text{NO}_2)_4$; diamido-diphenylmethane—

diphenylmethane-disulpho acid, $\text{C}_{12}\text{H}_{10}(\text{SO}_3\text{H})_2$; dinitro-benzophenone, $\text{C}_{12}\text{H}_8(\text{NO}_2)_2$; isodinitro-benzophenone, $\text{C}_{12}\text{H}_8(\text{NO}_2)_2\text{O}$.

This number contains a detailed account, written by A. Pinner, of the proceedings of the Chemical Section of the fiftieth annual meeting of the German Natural Philosophers and Physicians, held at Leipzig in August last; this meeting was very fully attended, and the proceedings bear testimony to the great progress made in chemical science in Germany. Many, if not all, of the papers read will be published in *extenso*.

NOTES AND QUERIES.

Oxychloride of Magnesium.—(Reply to T. F.)—The substance you allude to is not a cement, but a kind of artificial stone invented by Sorel. You will find ample information on the proper mode of preparing it in *Comptes Rendus*, vol. lxx., p. 102; *Mechanic's Magazine*, July, 1867, p. 52; *Dingler's Polytechnisches Journal*, Bd. 185, p. 292; and also in the *CHEMICAL NEWS*, vol. xxiii., p. 9.

Chemistry in India.—Mention was made in the *CHEMICAL NEWS* of India as a field for chemists to seek employment in. Could any of your readers inform me what work is there for a chemist to do? i.e., whether under Government, or academical? also as to where and to whom application for such employment should be made?—Ph.D.

PATENTS.

Communicated by Messrs. VAUGHAN and SOW, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

3017. N. Bickford, Exmouth, Devon, "An improvement in the manufacture of soap."—Petition recorded October 14, 1872.

3052. J. Hargreaves and T. Robinson, W'knes, Lancashire, "Improvements in apparatus employed in the manufacture of sulphates of soda and potassa."

3057. J. J. Shedlock, Upper Holloway, Middlesex, "Improvements in apparatus for the treatment of hydrocarbon gases and vapours for illuminating and heating purposes."—Petitions recorded October 16, 1872.

3080. H. Bethel, Victoria Street, Westminster, "Improvements in the treatment of beer, in order to prevent and remove acidity."—Petition recorded October 18, 1872.

3094. E. C. Nicholson, Herne Hill, Surrey, "Improvements in the production of colours for dyeing and printing."

VOL. XXVI. No. 677.

ON THE PRODUCTION OF FURFUROL BY THE ACTION OF HIGH-PRESSURE STEAM UPON WOOD.

By GREVILLE WILLIAMS, F.R.S.

My friend, Mr. George Fry, in the course of some laborious researches upon woody fibre, has had occasion repeatedly to subject fir wood to the action of water at an elevated temperature and pressure, and it is to him that I am indebted for the opportunity of examining some of the products. The experiments were each made on 100 lbs. of wood, in small blocks. They were placed in an iron cylinder surrounded with a steam jacket: 100 gallons of water were then introduced, and, the openings having been closed, high-pressure steam was admitted to the jacket until the manometer indicated a pressure of 100 lbs. to the inch in the interior of the cylinder. This was maintained for four hours. At the end of that time the liquid, which had become strongly acid, was run off through a cooling apparatus, and introduced into a rectifying still. By careful and repeated rectifications, two principal products were obtained in addition to the acid fluid: these were methylic alcohol and an oil.

The methylic alcohol was identified by conversion into oxalate of methyl.

The oil had a fragrant odour, resembling furfurol, but also recalling that of turpentine and cymene: 100 lbs. of wood yielded 10 ounces. Its specific gravity at 11° was 1.020. On rectification its boiling-point steadily rose from 163° to 216° C. On immersion in a freezing mixture it separated into two layers. The upper one was colourless, and had a specific gravity of 0.8855 at 11°; or, sensibly the same as that of turpentine. After rectification over sodium it yielded, on analysis, numbers intermediate between those of turpentine and cymene. Its odour also resembled that of a mixture of those substances. This hydrocarbon, or mixture of hydrocarbons, which is formed in very small quantity, is now under study. The lower layer had a specific gravity of 1.0784 at 11°. It gave the same reaction as furfurol with aniline. It was carefully rectified, and the portion boiling between 163° and 171° examined. On standing over sticks of potash a solid crust accumulated, which was separated by agitation. As thus obtained, the substance was in the form of minute colourless crystals: they were analysed with the following result:—

0.3473 grm. of substance gave 0.5072 grm. of carbonic acid, and 0.0770 grm. of water.

0.6140 grm. of substance gave 0.3606 grm. of sulphate of potassium.

Or, per cent—

Experiment.	Calculation.	
Carbon .. 39.83	C ₅ 60.00	39.97
Hydrogen .. 2.46	H ₃ 3.00	2.00
Potassium.. 26.37	K 39.14	26.05
Oxygen .. 31.34	O ₃ 64.00	31.98
100.00	166.14	100.00

The substance was, therefore, pyromucate of potassium, which is well known to be a product of the action of hydrate of potassium or pyromucic aldehyde (furfurol).

Although the conversion of the heavier oil into pyromucate of potassium might be considered sufficient evidence of its nature, I sought to confirm the result by the preparation of furfuramide, especially as such an experi-

ment would enable me approximatively to determine the amount of furfurol present in the crude oil. On treatment with excess of strong ammonia, and allowing the mixture to stand for 12 hours, it was converted into a mass of straw-coloured needles. These were filtered off, pressed between folds of filtering-paper, and gently dried. After re-crystallisation from alcohol, the following numbers were obtained on analysis:—

0.2488 grm. of substance gave 0.6111 grm. of carbonic acid, and 0.1098 grm. of water.

Experiment.	Calculation.	
Carbon .. 66.99	C ₁₅ 180	67.16
Hydrogen .. 4.90	H ₁₂ 12	4.48
Nitrogen .. —	N ₂ 28	10.45
Oxygen .. —	O ₃ 48	17.91
	268	100.00

The substance was, therefore, furfuramide. In order to obtain an idea of the amount of furfurol present in the oil, I made some experiments to determine the yield of furfuramide; the mean result of four experiments being that 100 parts of the crude oil gave 39.3 of furfuramide, corresponding to 42.3 per cent of furfurol.

Stenhouse, in the course of his admirable researches upon furfurol and its isomers, has shown that furfurol is formed on distilling sawdust with dilute sulphuric acid.* I have not, however, found any notice of its having been prepared by the action of water alone upon wood, and the fact of its production under these circumstances will probably tend to modify our views as to its derivation.

As the quantity of crude furfurol obtained in this manner will probably before long be very large, and as, from the nature of the process, it will all be saved, the process indicated will doubtless be the best source of furfurol at present known, until that which is produced in the preparation of munjeet and garancine is no longer allowed to escape.

November, 1872.

RESEARCHES ON THE ATOMIC WEIGHT OF THALLIUM.†

By WILLIAM CROOKES, F.R.S., &c.

In June, 1862, and in February, 1863, I had the honour to lay before the Royal Society communications on the subject of the then newly discovered metal, thallium. In these I gave an account of its occurrence, distribution, and the method of extraction from the ore, together with its physical characteristics and chemical properties; also I discussed the position of thallium among elementary bodies, and gave a series of analytical notes.

In the pages of the *Journal of the Chemical Society* for April 1, 1864, I collated all the information then extant, both from my own researches and from those of others, introducing qualitative descriptions of an extended series of the salts of the metal. I propose in the present paper to lay before the Royal Society the details and results of experiments which have engrossed much of my spare time during the last eight years, and which consist of very laborious researches on the atomic weight of thallium.

SECTION I.

On the Determination of Atomic Weights.

In determining accurately the atomic weight of a metal that stands so high in the scale as thallium, difficulties and sources of error which are comparatively small with elements of low atomic weight are magnified to serious proportions, and require more than ordinary care for their elimination. When so large a proportion of the compound

* Watts's "Chemical Dictionary," vol. ii., p. 751.

† Abstract of a Paper communicated to the Royal Society, June, 1872.

under analysis or synthesis consists of the body itself whose atomic weight is the one unknown quantity, it is evident that the almost unavoidable errors occasioned by impurity in the materials employed, the losses incident to imperfect manipulation, or the inaccuracies arising during the weighing from the omission of the corrections required by temperature, pressure, &c., will all find their way into the number which is finally considered to represent the atomic weight of the metal.

I have attempted two entirely different methods of arriving at the atomic weight of thallium. Had the results of these determinations differed materially, I should have extended the research to other methods; but as they so nearly agree, it appeared unnecessary to incur so great an additional expenditure of time and material with no reasonable prospect of getting any but confirmatory results. The first method, and that which I shall describe, consists in taking a known quantity of metallic thallium, dissolving it in nitric acid, and weighing the nitrate of thallium produced.

The second method consists in dissolving known quantities of sulphate of thallium in water, and ascertaining how much nitrate of barium is necessary to precipitate the sulphuric acid as sulphate of barium.

SECTION II.

Apparatus Employed.

The absolute weight of any substance may be found from its apparent weight in an atmosphere of 30 inches of mercury, and from its apparent weight under, say, 25 inches of mercury. But the best weightings are undoubtedly one in air at ordinary pressure and temperature, and one in a highly rarefied atmosphere,—it cannot be said *in vacuo*, owing to the difficulty of working under such a difference of pressure between the atmosphere of the balance and that surrounding it.

The Balances.

Two balances were used. That which I shall call the *air-balance* was made by Messrs. Keissler and Neu expressly for this work, and will clearly indicate a difference of 0.0001 of a grain when loaded with 1000 grains in each pan.

The second balance, which I shall call the *vacuum balance*, is almost a duplicate of the first, of 14 inch beam, with agate knife-edges and planes, made by Oertling. It is enclosed in a cast-iron case connected with an air-pump, and so arranged that I can readily weigh any substance in air of any desired density, the rarefaction being measured by a barometer gauge.

At first it was attempted to put nearly the correct weight into the pan, and then make the final adjustment by means of the rider. It was, however, soon found that a nearer approach to accuracy is to introduce a certain weight, and then to alter the pressure of the air until the balance shows equilibrium. Two weightings at different degrees of atmospheric pressure, varying by a considerable interval, give data upon which to calculate what the weight would be in a perfect vacuum.

The Weights.

A set of weights as ordinarily supplied by even the best instrument makers is never absolutely exact; however carefully they may be adjusted, the pieces of metal which respectively represent 1000 grains, 100 grains, 10 grains, &c., are only more or less approximations to the true weights. In most chemical analyses, the error arising from such inaccuracies in the weights used is so small in comparison to errors of manipulation, or to imperfections inherent in the chemical processes adopted, that it may generally be disregarded; but when the chemist has for his object the determination of an atomic weight, or is engaged in other researches demanding the highest refinement of accuracy which chemistry and physics can supply, then he is bound to neglect no correction which will increase the precision of the results.

The weights I employed were of platinum, made ex-

pressly for these investigations by Messrs. Johnson and Matthey. The platinum was quite pure; it was fused, cast, and then well hammered. The weights were adjusted by myself during May, June, July, and August, 1864: they were first roughly adjusted, and then the sp. gr. of each weight was taken. The weights were heated to redness in a bath of magnesia previous to ascertaining their sp. gr. The density of the larger weights was ascertained to the second place of decimals, and that of the smaller ones to the first place. The following are the results of the final adjustment, the weight *in vacuo* being calculated by the formula:—

W = weight in air,

w = weight in water,

a = sp. gr. of air as compared with water;

then—

$$x = \text{weight in } vacuo = \frac{W - aw}{1 - a},$$

where $a = 0.001225$, and

$$1 - a = 0.998775.$$

Results of the Adjustment of Standard Grain-weights (Platinum set).

* Riders.

The value of each weight in air, plus the weight of air displaced, is, of course, the weight *in vacuo*.

The Glass.

The flasks and vessels used were of the hardest Bohemian glass, and as thin as they could be employed. When practicable, vessels of old green German glass were used; neither this nor Bohemian glass is practically affected by reagents.

No cork or luting was employed in the distillations, &c.; in most cases the apparatus was blown in one piece, and the operations performed in a vacuum. The apparatus, which was weighed, was entirely composed of glass suspended with platinum wire loops: fingers were never allowed to touch it after the first weighing.

The weight of tubes, bulbs, and flasks, even of hard Bohemian glass, constantly diminishes when the glass is long heated in a spirit- or gas-flame; this loss may amount to several thousandths of a grain in the space of two hours when a bulb of Bohemian glass 3 inches in diameter is exposed to a decided red heat in a gas flame. Following the suggestion of Professor Stas, I have obviated this source of error by employing a bath of pure magnesia; and I find that the weight remains constant even at a nearly white heat. I have likewise employed baths of lime with similar satisfactory results.

The special apparatus that I have used are described in the processes in which they were required; I need scarcely say that in no case were materials of untried purity employed.

Improved Sprengel Vacuum Pump.

Before detailing the processes of the determination, it will be requisite to describe the means of producing a vacuum in the flasks and bulbs employed. In proceeding with the determinations, several additions and improvements have been made to the Sprengel pump as generally found in the laboratory. The apparatus, as thus arranged, is readily manageable, with certainty of obtaining a Torricellian vacuum.

SECTION III.

The Chemicals.

The detail of the processes of preparing the thallium and the reagents in a chemically pure state is too necessary to admit of useful abstraction.

SECTION IV.

Processes and Results.

The processes and manipulation necessary to the determination of an atomic weight are at all times difficult and delicate, but especially in the case of a metal such as thallium, so readily oxidisable. This strong tendency to combine with oxygen renders the ordinarily exact processes of weighing out pure metals inapplicable to the present purpose. The chances of contact with the oxygen of the atmosphere must be reduced to a minimum, and to this end it was found desirable to work *in vacuo*. For this purpose the series of bulbs shown in Fig. 11 have been blown. Pure thallium is introduced into *a*, the upper end of which is then sealed. The end *c* is also sealed up, and the horizontal tube *e* is connected to the Sprengel pump, and a vacuum obtained, the tube being then sealed at *f*. The thallium in *a* is now heated on a magnesia-bath to its point of fusion (561° F.), and when molten caused, by gently tilting the vessel, to flow by the narrow channel *d* into the lower bulb *b*, all oxide remaining in *a*. The channel *d* is now contracted before the blowpipe, and *a* removed. The bulbs then appear as in Fig. 12, and after cooling are carefully weighed in air and *in vacuo*. The fine point of a blowpipe-flame, caused to impinge upon the end of the tube at *g*, softens the glass, and the air, endeavouring to force its way into the bulbs, forms a capillary orifice. By heating the bulb, and immersing the orifice in the pure nitric acid, the acid is introduced into the bulbs *h* and the globe *b* until all the thallium has been dissolved. The most tedious part of the process then commences, the evaporation of the excess of free acid. For this purpose an apparatus is used of the form represented in Fig. 13: *a* is the apparatus, connected by a wide tube (*b*) and a narrower glass tube with a Woulfe's bottle (*c*); this is in connection with a Bunsen's water pump (*d*), having 15 feet fall of water, and capable of producing an exhaustion equal to 10 inches of mercury. In the course of time the nitrate of thallium is left in the form of dry white crystals. The pump is then stopped, and air allowed to enter the apparatus by opening the pinch-cock, *e*, connected with the chloride of calcium tubes, *f*. The nitrate of thallium is then treated with a solution of oxalic acid to reduce any perntrate that may be formed, the crystals dried, fused, dissolved in water, again allowed to crystallise, the evaporation of the water being repeated under diminished pressure. When there is no longer a loss of weight, the nitrate of thallium is finally weighed, the air being exhausted from the apparatus. The apparatus is now of the form shown in Fig. 14, and is weighed at two different atmospheric pressures. The nitrate of thallium having been afterwards removed, the apparatus is alone weighed at two different pressures. There have thus been obtained:—

- α. The weight of the glass+thallium.
- β. The weight of the glass+nitrate of thallium.
- γ. The weight of the glass alone.

Particulars of these weights are given in the next section.

SECTION V.

Calculation of the Results.

The formulæ by which I have calculated the weights from weighings at two different atmospheric pressures are given at length in the full description of the processes that I have the honour to submit to the Royal Society.

Collecting the data, we have:—

True weight of thallium <i>in vacuo</i> ..	grs. = 183.7932
True weight of nitrate of thallium <i>in vacuo</i> ..	= 239.64665
True weight of glass ..	= 766.133831
(a) Weight of thallium according to true value of weights in air ..	= 183.783921
(b) Weight of nitrate of thallium in air (1005.425937-765.814578) ..	= 239.611359
(c) Weight of glass &c. in air ..	= 765.814578
Weights employed to balance (a) ..	= 183.8099
Weights employed to balance (b) (1005.4364-765.8081) ..	= 239.6283
Weights employed to balance (c) ..	= 765.8081

The reduction of the atomic weight from these data becomes a case of simple proportion; but the values found are absolute in so far only as the atomic weights of nitrogen and oxygen are correct. The atomic weights of nitrogen and oxygen have been usually represented by the numbers 14 and 16; but Professor Stas found these elements represented, according to observation, by—

Oxygen (O ₃) ..	= 47.880
Nitrogen ..	= 14.009

or nitric acid NO₃ = 61.889. According to the old equivalents, NO₆ = 62.

Taking as data the series of weighings *in vacuo*, the quantity of nitric acid required to convert the thallium into nitrate is (239.646066-183.790232)=55.855834 grs.

We have, then, with Professor Stas's determination of the atomic weights of nitrogen and oxygen, the following proportion:—

Weight of Nitric Acid.	Weight of Thallium.	Atomic Weight of Nitric Acid.	Atomic Weight of Thallium.
55.855834	: 183.790232	:: 61.889	: x;
∴ x = 203.642.			

Let us see what would be the atomic weight of thallium if one or other of the corrections introduced into the above determinations had been omitted. The use of the old equivalent (= 62) for nitric acid, with the data derived from the weighings *in vacuo*, gives—

$$55.855834 : 183.790232 :: 62 : 204.007$$

as the atomic weight; but I cannot admit this number to be so nearly correct as 203.642.

If we take the corrected weighings in air of ordinary density, we have, with NO₃=61.889,

$$\begin{aligned} &203.738. \\ \text{With NO}_6=62, &204.103. \end{aligned}$$

Accepting the uncorrected weights, observed in air, we have with NO₃=61.889,

$$\begin{aligned} &203.162. \\ \text{With NO}_6=62, &204.165. \end{aligned}$$

The error of the last deduction, +0.523, is sufficiently large to show the necessity of neglecting no precaution in chemical manipulation, especially in a determination of this character. The largeness of these errors have an immediate bearing upon quantitative analysis; for they show that from data ordinarily given very varying results may be obtained. Chemists have to deal with much smaller quantities than a quarter per cent, particularly in organic analysis, where such a difference from the truth may lead to very erroneous reasoning.

RESULTS.

Ten results of the most trustworthy weighings (with $\text{NO}_3 = 61.889$) are* :—

Deter- mination.	True Weights in vacuo.			
	Weight of Thallium taken.	Weight of Nitrate of Thallium + Glass.	Weight of Glass.	Calculated Atomic Weight from these data.
	grs.	grs.	grs.	grs.
A.	497.972995	1121.851852	472.557319	203.666
B.	293.193507	1111.387014	729.082713	203.628
C.	288.562777	971.214142	594.949719	203.632
D.	324.963740	1142.569408	718.849078	203.649
†E.	183.790232	1005.366796	766.133831	203.642
F.	190.842532	997.334615	748.491271	203.636
G.	195.544324	1022.176679	767.203451	203.639
H.	201.856345	1013.480135	750.334401	203.650
I.	295.683523	1153.947672	768.403621	203.644
K.	299.203036	1159.870052	769.734201	203.638

I wish it to be noted that I have made determinations with various weights of thallium. In ordinary analysis chemists are satisfied to take 5 or 10 grains of the substance under investigation: here I have gone to the very highest weight that can be entrusted with safety to the balance. The lowest weight of thallium taken is 183.790232 grains, the heaviest 497.972995 grains, the remaining determinations varying between these limits. It is hardly necessary to say that the purpose has been to eliminate the error arising from manipulation with small quantities, and to produce such variety in the results as renders the chances of coincidence of very small value.

Let me now tabulate the results of the determinations, with the view to ascertain severally their degree of approximation to the arithmetic mean :—

A.	203.666	+0.024
B.	203.628	-0.014
C.	203.632	-0.010
D.	203.649	+0.007
E.	203.642	+0.000
F.	203.636	-0.006
G.	203.639	-0.003
H.	203.650	+0.003
I.	203.644	+0.002
K.	203.638	-0.004

The arithmetic mean of the ten observations is

$$a = \frac{2036.424}{10} = 203.642.$$

The probable error is 0.0022; and the probability that the true value lies between 203.632 and 203.652 is 0.99808, certainty being represented by unity.

I may therefore conclude that the atomic weight of thallium is, within the limits of error (as small as possible) of observation,—

$$203.642$$

Professor Stas has shown the hypothesis of Prout—that the atomic weights of the elements are severally multiples of the atomic weight of hydrogen—to be without the corroboration of experimental result. This view of the hypothesis is further borne out in the present investigation; for the number 203.642 cannot, within the limit of what has been shown to be the probable error, by any liberty be made to follow the hypothesis. Without doubt, when the atomic weights of all the metals are re-determined according to the standard of recent scientific method, it will be found that there are more exceptions to the hypothesis than commonly considered. Marignac gives, in his confirmatory discussion of Stas's experiments, and in his own results with calcium (40.21), lanthanum (94.13), strontium (87.25), analogous opposed evidence, as in the case of the weight found for thallium.

* It should be noted that the arithmetic mean of all the readings, including the highest as well as the lowest result, in which doubt might arise as to success in manipulation, is 203.6.

† Fully illustrated in the paper.

I have thus striven to eliminate all erroneous influence in the number I submit to the Royal Society as the atomic weight of thallium; and I shall be amply rewarded for my long labour if I can know that the determination has secured to researches of this character a nearer approach to the standard of truth.

The drawings appended to the complete paper comprise copies of :—

- Fig. 1. The case of the vacuum balance.
- The improved Sprengel vacuum pump.
- Apparatus for preparing pure water under diminished pressure.
- Apparatus for preparing nitric acid under diminished pressure.
- Apparatus for preparing oxalic acid under diminished pressure.
- Apparatus for preparing sulphuric acid under diminished pressure.
- Stoppered tube in which thallium was weighed in the early determinations.
- A series of bulbs.*
- Another series of bulbs.*
- Apparatus for sealing up thallium in hydrogen.
- The first stage of selected glass apparatus.*
- The second stage of selected glass apparatus.*
- The Bunsen water pump and drying apparatus.
- The third stage of selected glass apparatus.*

SOLVENTS FOR INDIGO.

By Dr. E. JACOBSEN.

SOME new solvents for indigo have lately been given by De Aguiar and Baeyer, and by Professor Wartha. To these I will also add a few which I have discovered. That aniline will dissolve indigo has been known several years, from my own experiments; but an equally good solvent for indigo is nitrobenzol, which, when heated with indigo, is coloured a deep violet-blue, and on cooling deposits flaky crystals, and then appears dark red, probably from red indigo.

In greater or less quantities, the following substances dissolve indigo at their boiling-points :—

Castor oil, acetone, hydrate of chloral, camphor, oil of turpentine, balsam of copaiba, cedar oil (oil of Juniper virgin), amylic alcohol, oil of lavender, white bees'-wax, Japanese vegetable wax, and Caranba wax (from this last small flaky crystals precipitate).

The higher the boiling-point of the solvent, the redder is the appearance of the solution; so that bodies like acetone, amylic alcohol, and hydrate of chloral give a clear blue. Castor oil, cedar oil, &c., a violet-blue, and the different kinds of wax a purple-red solution. If kept for a short time at the boiling-point with white wax, the colour changes from scarlet to orange, and at last to a brown. The indigo is reduced by the formation of acrolein, and the solution retains its brown colour even on the addition of gasoline.

If powdered indigo is added to melting picric acid, the former will be decomposed with deflagration.—*American Chemist.*

University of London.—The following are lists of the candidates who have passed the recent second B.Sc. Examination:—*First Division.* Edward Albert Butler, B.A., private study; Charles Callaway, M.A., Cheshunt College; John Henry Poynting, Owens College; Ebenezer Geer Russell, First M.B., Guy's Hospital; Robert Harold Ainsworth Schofield, B.A., Lincoln College, Oxford, and Owens.—*Second Division.* Robert William Atkinson, University College and Royal School of Mines; Thomas Carnelley, Owens College; Alexander Irving, B.A., private study and School of Mines; Henry Elthington Price, private study.

* For the conversion of thallium into nitrate of thallium.

ON THE ECLIPSE EXPEDITION, 1871.*

By J. NORMAN LOCKYER, F.R.S., M.R.I.

(Concluded from p. 226).

I MUST now state very briefly some of the results of our work; and first, the certain results.

We were able to make out the structure of the corona. We know all about the corona so far as the structure of its lower brighter strata, that portion, viz., which I referred to in my lecture last year as being visible both before and after totality, is concerned. You may define it as consisting of cool prominences; that is to say, if you examine a prominence any day, without waiting for an eclipse, and then go to an eclipse and examine the lower portion of the corona, you will find the same phenomena, *minus* the brightness. You find the delicate thread-like filaments which you are now all so familiar with in prominences—filaments which were first thrown on a screen in this theatre; the cloudy light masses, the mottling, the nebulous structure, are all absolutely produced in the corona, as far as I could see it with a telescope with an aperture of 6½ inches; and I may add that the portion some five minutes round the sun reminded me forcibly in parts of the nebula of Orion, and of that surrounding η Argus, as depicted by Sir John Herschel, in his Cape observations.

We have shown that the idea that we did not get hydrogen above 10 seconds above the sun is erroneous; for we obtained evidence that hydrogen exists to a height of 8 or 10 minutes at least above the sun; and I need not tell you the extreme importance of this determination. One of the proofs we have of that lies in this diagram, showing the observations made by Professor Respighi, armed with an instrument the principle of which I hope you are now familiar with.

Just after the sun disappeared, Professor Respighi employed this prism to determine the materials of which the prominences which were then being eclipsed were composed; and he got the prominences shaped out in red, yellow, in blue, and in violet light, a background of impure spectrum filling the field; and then, as the moon swept over the prominences, these images became invisible. He saw the impure spectrum and the yellow and violet rings gradually die out, and then three bright and broad rings, painted in red, green, and blue, gradually form in the field of view of his instrument; and as long as the more brilliant prominences were invisible on both sides of the sun, he saw these magnificent rings, which threw him in a state of ecstasy. And well they might.

These rings were formed by C and F, which shows us that hydrogen extends at least 7 minutes high, for had we not been dealing with hydrogen we should have got a yellow ring as well, because the substance which underlies the hydrogen is more brilliant than the hydrogen itself, and in addition to the red ring and the blue ring, which indicate the spectrum of hydrogen, he saw a bright green ring, much more brilliant than the others, built up by the unknown substance which gives us the Kirchhoff line, 1474.

Now, at the time that Professor Respighi was observing these beautiful rings by means of a single prism and a telescope of some 4 inches aperture, some 300 miles away from him—he was at Poodocottah, and I was at Bekul—I had arranged the train of prisms which you see here so that the light of the sun should enter the first one, and after leaving the last one should enter my eye. And what I saw is shown, side by side with Respighi's observations, in this diagram, in which I have separated the rings somewhat, so that there should be less confusion than in the actual observation. Here is Professor Respighi's first observation. He gets indications of C, D*, F, and the hydrogen line near G. He was observing the very lowest, brightest region of all, and therefore 1474 was obliterated by the brightness of the continuous spectrum; but, as the

eclipse went on, D* was entirely obliterated, and afterwards he got C and F building up rings together with 1474, which was not represented in the lower regions of the prominence—not because it was not there, but because, as I have already insisted, of the extreme brilliancy of the background. Now my observation was made immediately, as it were, between the two observations of Professor Respighi's. Let me show the observations together.

Respighi ..	C D*	FG	Prominences at beginning of eclipse.
Lockyer ..	C	1474 FG	Corona at 80 seconds from commencement.
Respighi ..	C	1474 F	Corona at mid eclipse.

Note that I had no object-glass to collect light, but that I had more prisms to disperse it; so that with me the rings were not so high as those observed by Respighi, because I had not so much light to work with: but such as they were I saw them better, because the continuous spectrum was more dispersed, and because, with my dispersion, the rings—the images of the corona—therefore did not so much overlap. Hence, doubtless Respighi missed the violet ring which I saw, so faint, however, that both that and 1474 were almost invisible, while C shot out with marvellous brilliancy, and D* was absent.

These observations thus tend to show, therefore, that instead of the element—the line of which corresponds with 1474—existing alone just above the prominences, the hydrogen accompanies it to what may be termed a great height above the more intensely heated lower levels of the chromosphere, including the prominences in which the lower vapours are thrown a greater height. With a spectroscope of small dispersion attached to the largest mirror of smallest focus which I could obtain in England, the gaseous nature of the spectrum, as indicated by its structure, that is, bands of light and darker intervals, as distinguished from a continuous spectrum properly so called, was also rendered evident.

These are results of the highest importance, which alone are worth all the anxiety and labour connected with the expedition.

But there is more behind.

The photographic operations (part of the expense of which was borne by Lord Lindsay) were most satisfactory, and the solar corona was photographed to a greater height than it was observed by the spectroscope, and with details which were not observed in the spectroscope.

Mr. Davis was fortunate enough to take an admirable series of five photographs at Bekul, and Captain Hogg also obtained some at Jaffna; but I am sorry to say the latter lack somewhat in detail.

I have prepared two lamps, because I am anxious to exhibit the photographs two at a time, that you may compare one with the other. [This was done.] You see that, so far as the camera goes—and mark this well—the corona was almost changeless during the whole period of totality; this is true, not only for one place, but for all the places at which it was photographed.

I now exhibit two other photographs—one taken at Jaffna, and the other at Ootacamund. Actinically, the corona was the same and practically changeless at all the stations. You see that, though not so obvious as in the other case, there is the same similarity.

Before I leave the actinic corona, I am anxious to show you an image of it, taken during the American eclipse of 1869 in a camera exposed to the sun during the whole of the totality; to a certain extent, in our recent photographs we have reproduced what was photographed in 1869.

The solar nature of most, if not all, of the corona recorded on the plates is established by the fact that the plates, taken in different places, and both at the beginning and end, of totality, closely resemble each other, and much of the exterior detailed structure is a continuation of that observed in the inner portion independently determined by the spectroscope to belong to the sun,

* A Lecture delivered before the Royal Institution of Great Britain.

While both in the prism and the 6 $\frac{1}{2}$ inch equatorial the corona seemed to form pretty regular rings round the dark moon, of different heights according to the amount of light utilised by the instrument, on the photographic plates. The corona, which, as I have before stated, exceeds the limits actually seen in the instrument I have named, has a very irregular, somewhat stellate outline, most marked breaks or rifts (*ignored by the spectroscopes*), occurring near the sun's poles, a fact perhaps connected with the other fact that the most active and most brilliant prominences rarely occur there.

From the photographs in which the corona is depicted actinically, we pass to the drawings in which it is depicted visually. I would first call attention to two drawings made by Mr. Holiday, who formed part of the expedition, and in whose eye everyone who knows him will have every confidence.

First there is a drawing made at the commencement of the totality, and then a drawing made at the end. There is a wonderful difference between the drawings; the corona is in them very much more extensive than is represented actinically on our plates.

Here is another drawing, made by Captain Tupman, in which again we have something absolutely different from the photographs and from Mr. Holiday's sketches, inasmuch as we get an infinite number of dark lines extending down to the moon, and a greater extension than in the photographs, though in radial places the shape of the actinic corona and some of its details are shown.

Now the corona, as it appeared to me with the naked eye, was nothing but an assemblage of bright and dark lines: it lacked all the structure of the photographs, and appeared larger; and I have asked myself whether these lines do not in some way depend on the size of the telescope, or the absence of a telescope. It seems as if observations of the corona with the naked eye, or with a telescope of small power, may give us such lines; but that, when we use a telescope of large power, it will give, close to the moon, the structure to which I have referred, and abolish the exterior structure altogether, leaving a ring round the dark body of the moon such as Professor Respighi and myself saw in our prisms; and in the 6 inch telescope, in which the light was reduced by high magnification, so as to bring the corona to a definite ring some 5 minutes high; while Professor Respighi, using a 4 inch telescope and less magnifying power, brought the corona down to a ring something like 7 minutes high.

And here we have an important connection between spectroscopic and telescopic work. If we employ a telescope in which the light is small or is reduced by high magnification, we bring the corona to a definite ring, and perhaps here we have the origin of the "ring-formed" coronas.

Many instances of changing rays, like those seen by Plantamour in 1860, were recorded by observers in whom I have every confidence. One observer noted that the rays revolved and disappeared over the rifts.

We have next to deal with the polariscopic observations.

Mr. Lewis, in sweeping round the corona at a distance of 6' or 7' from the sun's limb, using a pair of compensating quartz wedges as an analyser, which remained parallel to itself while the telescope swept round, observed the bands gradually change in intensity, then disappear, bands of a complementary character afterwards appearing, thereby indicating radial polarisation.

Dr. Thompson at Bekul saw strong traces of atmospheric, but none of radial, polarisation, with a Savart. With the same class of instrument the result obtained by myself was precisely similar; while on turning in the Biquartz, at the top and bottom of the image of the corona, i.e., near the sun's equator, faint traces of radial polarisation were perceptible for a short distance from the moon's limb. Captain Tupman, who observed with the polariscope after totality, announces strong radial polarisation extending to a very considerable distance from the dark moon.

Leaving the extreme outside of the corona as a question to be determined at some future time—and it can well wait—let us come to the base of the corona, and deal with the region to which I have already referred, close to the sun.

What was the general conclusion at which we arrived on this important point? Before I state it, let me tell you the instrumental conditions of the inquiry. We can use such a spectroscope as the one with which you are all familiar, and so arrange matters that the slit shall be carried by a clock, so that it may follow accurately the edge of the moon; but if the least variation in the rate of motion takes place, the observation is rendered almost valueless. But if we employ a spectroscope in which we sum up the light—do not localise the light, but throw it together—it does not matter whether your clock goes well or not, you are certain to have a result worthy of credit. But if you employ such an instrument as Professor Respighi employed, and abolish the slit altogether, the weight of any observations made with such conditions is very great.

Captain Maclear, who was observing with me at Bekul, has undoubtedly shown that, when the light of our atmosphere is cut off by the interposition of the dark moon, we see very many more bright lines than we do when this is not the case, the lines being of unequal height.

Mr. Pringle, also at Bekul, showed that at the end of totality many lines flashed into one of these instruments, carried under these difficult conditions.

Captain Fyers, the Surveyor-General of Ceylon, observing with a spectroscope of the second kind, saw something like a reversal of all the lines at the beginning, but nothing of the kind at the end.

Mr. Fergusson, observing with a similar instrument, saw reversal neither at the beginning nor the end.

Mr. Mosely, whose observations are of great weight, says that at the beginning of the eclipse he did not see this reversal of lines. Whether it was visible at the end he could not tell, because at the close the slit had travelled off the edge of the moon.

Professor Respighi, using no slit whatever, and being under the best conditions for seeing the reversal of the lines, certainly did not see it at the beginning, but he considers he saw it at the end, though about this he is doubtful.

From the foregoing general statement of the observations made on the eclipse of last year, it will be seen that knowledge has been very greatly advanced, and that most important data have been obtained to aid in the discussion of former observations. Further, many of the questions raised by the recent observations make it imperatively necessary that future eclipses should be carefully observed, as periodic changes in the corona may then possibly be found to occur. In these observations the instruments above described should be considered normal, and they should be added to as much as possible.

I had intended, if time had permitted me, to point out how much better we are prepared for the observation of an eclipse now than we were when we went to India, and how a system of photograph record should be introduced into the spectroscopic and polariscopic work; but time will not allow me to do more than suggest this interesting topic. I am anxious, however, that you should allow me one minute more to say how very grateful we feel for the assistance rendered by all we met, to which assistance so much of our success must be ascribed. I wish thus publicly to express the extreme gratitude of everyone of our Expedition to the authorities in India and in Ceylon for the assistance we received from them; and our sorrow that Admiral Cockburn, a warm and well-known friend to science, who placed his flag-ship at the disposal of the expedition, and the Viceroy, whose influence in our favour was felt in every region of India whither our parties went, and to whom we gave up our ship, are now, alas! beyond the expression of our thanks. We are also anxious to express our obligations to the directors and officers of

the Peninsular and Oriental Company for the magnificent way in which they aided us. If they had not assisted us as they did, science would have gained very much less than she has done from the observations of the last eclipse.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 7th, 1872.

Prof. WILLIAMSON, Vice-President, in the Chair.

WHEN Messrs. R. Weaver, C.E., W. W. Fisher, Edward Kinch, and Walter Weldon, had been formally admitted Members of the Society, and the donations announced, the following names were read for the first time:—Messrs. Kigonari H. Yoshida, Francis H. Hobler, Sydney Lupton, E. W. Prevost, Ph.D., Thomas Williams, T. D. Fitmal, Joseph Lanson Wills, A. Percy Smith, Philip Braham, John Hollings Mitchell, Robert William Jones, A. Cameron Bruce, M.A.

For the third time—Archibald Liversidge, Esq., who was ballotted for and duly elected.

The first paper was "*On the Action of Charcoal on Organic Nitrogen*," by E. C. STANFORD. The author, in 1869, proposed a method of mixing excreta, fish offal, and other offensive matter, with charcoal, so as to deodorise them, and when dry to heat the product in retorts, thus obtaining the whole of the nitrogen as ammonia. Experiments were made to ascertain the truth of the current opinion that nitrogenous matters in contact with charcoal become oxidised, giving rise to nitric acid, which would of course render the process valueless. For this purpose mixtures of excreta and decaying animal matter with three different varieties of charcoal were prepared, and examined at different intervals during twenty-one months, but no nitric acid could be detected. The author therefore infers that charcoal mixed with nitrogenous organic matter acts simply as a dryer, and not as an oxidising agent, and that for all practical purposes there is but little loss of nitrogen in such mixtures.

The CHAIRMAN said it was interesting to find, from the records of the author's experiments on this important point, that the loss of nitrogen was so small. This method would doubtless be of great practical importance, especially as those products of oxidation generally believed to be formed by the action of the air did not occur.

There was also another short paper by Mr. E. C. STANFORD, "*On Iona Pebbles*." These pebbles, of which analyses are given, are a variety of non-aluminous serpentine, of an olive-green colour.

Prof. MASKELYNE observed that not only the pebbles mentioned, but also other Iona minerals, had already been analysed, and the results published in the *Journal* of the Society.

The CHAIRMAN called the attention of the members to a beautiful specimen of bromocamphor made by Mr. Williams, which was remarkable as having been prepared at the ordinary pressure.

Mr. WILLIAMS said it was only necessary to keep the mixture of bromine and camphor at 130°, and, when the action was complete, to dissolve the crude substance in hot petroleum. On cooling the bromocamphor crystallised out, and the camphor remained in solution. Two or three crystallisations from alcohol rendered it pure. The large amount of hydrobromic acid given off rendered it much safer to operate at the ordinary pressure than in closed vessels. The speaker added that it was used medicinally, as a nerve sedative, in such diseases as *delirium tremens*.

A communication entitled "*Mineralogical Notices*," by Prof. STORY MASKELYNE and Dr. FLIGHT, was then read

by the former. There were many specimens in the British Museum which were unique or almost so, and it was desirable to have them analysed, to ascertain what they really were, so as to discover, if possible, new localities for them, or, if they were not definite minerals, to abolish them. The first mentioned was isopyre, of which there were several specimens, varying in appearance but differing considerably in composition: probably the presence of ferrous oxide in all these varieties of opal may explain the mineralogical similarity to which their association, under the name of isopyre in our collections, is due.

A mineral named Percylite, after Dr. Percy, originally from Sonora, in Mexico, has also been obtained from another locality, namely, South Africa. That from Sonora had a notable amount of gold disseminated throughout the specimen, whilst the one from Africa contained horn silver. The author had also procured from South Africa a mineral of a chestnut-brown colour, which turned out to be remarkably pure vanadite. He also noticed some new Cornish minerals, a uranite from Redruth, and a specimen of a remarkable bluish-green, botryoidal, lustrous mineral, associated with quartz: on examination it was found to have the composition of prasine or ethlite, a member of the pseudo-malachite group, one of which—the normal pseudo-malachite—contains three equivalents of cupric hydrate, the others one or more equivalents of water substituted for the same number of equivalents of cupric hydrate.

Dr. WILLIAMSON thanked the authors for their valuable instalment of mineralogical notices from the British Museum, and remarked that it was especially pleasant to chemists to hear that at least one mineral had been done away with. Chemically it would be of great interest if it were established that one molecule of water were replaced by one of cupric hydrate; for his part, he should have been inclined to imagine that one of cupric hydrate would have replaced two of water.

Prof. MASKELYNE replied that he did not mean to say that there was an actual replacement, but that in this group of minerals one contained three of water, another two water and one cupric hydrate, a third one water and two cupric hydrate, and so on.

Mr. SPILLER remarked that he was a pupil of Dr. Percy at the time that he was examining percylite, and some experiments had been made with the object of preparing it artificially, by immersing plates of lead in solutions containing cupric chloride and sulphates; perhaps Prof. Maskelyne could say whether this oxychloride of lead and copper had yet been produced artificially, like atacamite, in the flues at the great copper-mines in Chili.

Mr. ROBERTS then read a paper "*On the Specific Heat of Occluded Hydrogen*," by W. CHANDLER ROBERTS and C. R. A. WRIGHT, D.Sc., in which he stated that, until the experiments were concluded, they desired to abstain as much as possible from giving numerical values, but they might mention that the values for the specific heat varied greatly,—when the palladium was saturated with the gas it was as low as 4 between 0° and 100°; and that when the charge was low the specific heat was as high as 8 or 9,—which might, perhaps, be explained if we regard the first portions of gas absorbed as liquefied and the later portions as solid, the specific heat of a liquid body being greater than when it is in the solid state.

Professor WILLIAMSON said the Society would await with interest further particulars on this subject, as until the numerical data were given it could not be discussed. He would like to know, however, how far the experimental errors were likely to affect the numbers given.

Dr. WRIGHT replied that generally two or three experiments were made of each kind, and the difference between the results was extremely small, although he might observe that when the palladium had once been charged and the hydrogen pumped out, and then re-charged, a certain difference was observable in the second experiment, probably attributable to irregularity in the distribution of the

hydrogen through the metal. But the main fact that there was a difference in the specific heat of the occluded hydrogen when the charge of the palladium was high, and when it was low was satisfactorily established.

Mr. J. A. R. NEWLANDS then made a communication "*On a Means of Preventing Explosions in Coal-Mines*," in which, after remarking that diminished atmospheric pressure was frequently the cause of explosion in coal-mines proposed to obviate this by having the upcast and downcast shafts covered by air-tight chambers, the one furnished with an outlet valve, and the other connected with pumping machines to force air into the mine. This might be done by air pumps, or by a ventilating fan, or by the Sprengel pump. In case of an escape of fire-damp a diminished pressure might first be produced in the mine, and the liberated fire-damp subsequently expelled by driving a current of air through the workings.

The CHAIRMAN said it was a matter of great importance and interest, not only to chemists, but to the public at large; the principle seemed to be a sound one, but he could not say whether the mechanical means would answer the purpose.

The last paper was "*On some Possible Reactions that yielded Negative Results*," by Dr. C. R. A. WRIGHT, giving an account of numerous reactions the author had tried but which had not given the desired results. He had made this communication with the view of saving the labour of other chemists who feel disposed to examine these reactions.

Professor WILLIAMSON said that chemists were not sufficiently in the habit of communicating negative results, for if they did it would often save much valuable time and labour. It was quite as much a chemical fact that no reaction took place under given circumstances, as when the reaction yielded some definite result. He supposed it was want of moral courage which prevented chemists recording their failures, and in this Dr. Wright had set us a good example.

The meeting was then adjourned until Thursday, the 21st inst., when Mr. Perkin will read a paper on "*Anthra-flavic Acid*."

CHEMICO-AGRICULTURAL SOCIETY OF ULSTER.

THE usual monthly meeting of this Society was held on the 1st inst. in their rooms, Arthur Street, Major Crawford, J.P., presiding. The other members present were—Dr. Ritchie, J.P.; Dr. Hodges; W. R. Jackson, Esq.; and Robert M'Calmont, Esq.

New Members.

Dr. HODGES said that he had very much pleasure in informing them that since the last meeting he had received a letter from Sir Richard Wallace intimating his intention of subscribing £10 annually to the funds of the Society, and he also stated that he expected to occasionally take part in their meetings. He, therefore, proposed that Sir Richard Wallace be appointed a member of the Society.

The motion was unanimously adopted.

J. B. Price, Esq., J.P., was also appointed a member of the Society.

Discovery of the rare Metal Vanadium in the Iron Ores of the County Antrim.

Dr. HODGES stated that, in the alluvial basalt and iron beds of the North of Antrim, the presence of the metal titanium had been noticed by Mr. Riley, and also reported by himself. He wished, however, to make known to the Society that he had, a great many years ago, directed the attention of Mr. Fisher, the lessee of some of the rich ores of Glenravel, to the occurrence of another rare metal, vanadium, in specimens of the ores submitted to him for examination. The existence of vanadium in Irish ores had not previously been detected. The late Professor Thomas Thompson, of Glasgow, discovered it in combination with

lead in a mineral brought to him by the well-known veteran mineral explorer, Pat Doran, from an old abandoned lead mine in the County of Wicklow. It has also lately been discovered in the basalt from the Giant's Causeway by Mr. Robert Apjohn.

The Whisky of the County Down.

With respect to his reports on the adulteration of whisky, Dr. Hodges directed attention to some portions of his remarks, which were not so fully given as he wished, and also to some inaccuracies in the published accounts of the last Council meeting. In general their meetings were reported with surprising accuracy, and it was not remarkable that occasionally errors should creep up. Thus, in the last report, he was made to state that the buttermilk which he had submitted to analysis contained tobacco, 9 and 10 per cent of cream, and some samples as much as 21 per cent. This must have surprised some of the members. In reference to the compound used to produce a cheap whisky, and which he stated had been hawked about in County Down, and sold by persons who had no licence, at fairs and other public gatherings, he had received a communication from Mr. James Crawford, J.P., who considered it fair that the present publicans of Crossgar should be exonerated from any suspicion of selling adulterated whisky. The contents of the bottle which, several years ago, had been brought to him by a constable, and which was suspected to be used for the adulteration of whisky, and forwarded for analysis, had been taken in the house of a man who went shortly afterwards to America, so that the circumstance cannot cast any slur on the present publicans of Crossgar, in whose possession no adulterated whisky had been found. With respect to the analyses of articles of food and drink, he (Dr. Hodges) wished to correct the opinion which some people appeared to entertain that it was his duty as borough analyst to search for adulterated articles. This, however, was a mistake; he had nothing to do with the inspection of food, and was merely required to examine articles forwarded to him by the officers appointed by the Town Council. With respect to the extent to which the adulteration of whisky is carried on in some places, it appears that in this country we are not so culpable as our neighbours in Scotland. The *Glasgow Weekly Mail*, of October 5, reports that, of thirty specimens examined, only two were genuine, and several of them were made up of the potent ingredients which were given in the receipt, and referred to at a former meeting. One specimen of the Glasgow whisky, obtained from an itinerant shebeener, is described as having a strongly naphthalitic taste, and containing free and combined sulphuric acid no less than 60 grains per gallon; copper as sulphate (bluestone); also present, shellac, turpentine, methylic and ethylic alcohols of specific gravity 820; about 75 ozs. per gallon. The reporter adds that it contains no whisky, the principal ingredients being Berlin wood spirit, naphtha, and water, the other articles being added to increase the bite.

Cromac Water.

Dr. HODGES said that he was continuing his examinations of the waters in Belfast and the neighbourhood. He had found considerable difference in the composition of the well waters in the Cromac district. The amount of mineral matters, especially of common salt, was much greater in some of the wells than in others. All the samples, however, were remarkably free from nitrogenised impurities. Dr. Hodges stated that a sample lately examined by his son contained per gallon 17.127 grs. of mineral and saline matters, consisting of—Silica, 0.770; oxide of iron, 0.875; carbonate of lime, 1.269; carbonate of magnesia, 3.423; sulphate of lime, 5.270; chloride of potassium, 0.622; chloride of sodium (salt), 4.410. Total, 17.128.

New Patent Ink.

Dr. HODGES intimated that he had taken out a patent for an improved ink for printing bank cheques. He ex-

plained that it was quite possible, by application of a chemical compound, to obliterate any writing on a cheque without defacing the lithographed or engraved portion of it, and numerous frauds had been effected on account of this fact. Dr. Hodges produced a cheque of the Ulster Bank, printed in the ink which he has patented, and showed that if any attempt was made to obliterate the writing on the cheque the lithographed portion would also be defaced, and any attempted fraud thereby immediately detected.

The members expressed a favourable opinion on the utility of the invention.

CORRESPONDENCE.

A MODIFICATION OF MOHR'S BURETTE.

To the Editor of the Chemical News.

SIR,—I wish to add my testimony to that of your other correspondents as to the advantage for small burettes of the modification in question, which consists in regulating the ingress of air at the top of the burette instead of the egress of liquid at the bottom.

I have never found any difficulty with this form of burette, either through changes in the temperature of the laboratory, or in delivering the liquid as required, or owing to leakage.

The screw-clamp which regulates the admission of air may conveniently be wired on to the holder which supports the burette. It is advantageous, also, to fuse a taper spout, $\frac{1}{4}$ inches long, on to the end of the burette, which is better suited than the end of the burette itself (as Mohr's burettes are commonly made) for dipping into a beaker containing the test-fluid. The taper ending serves also, by its capillarity, to render the liquid less movable by small changes of atmospheric pressure.

I have seen few burettes with stopcocks, where the nature of the test-fluid does not admit of a lubricant, as little liable to drip as a burette thus mounted; and filling by upward motion is much more convenient than filling from the top.—I am, &c.,

A. VERNON HARCOURT.

Christ Church College, Oxford.

THE UTILITY OF ODOURS TO PLANTS IN RELATION TO RADIANT HEAT.

To the Editor of the Chemical News.

SIR,—The interesting speculations of your correspondent, Mr. W. H. Olley, in the CHEMICAL NEWS, vol. xxvi., p. 202, as to the part played by the odours of flowers and fruit in tendency to preserve a congenial temperature around them, are probably based in truth. His views are, however, not new. Whether Prof. Tyndall himself saw that those views followed from his researches on the heat-jacketing effects of vapour, I know not; he may possibly have done so, although not referring to the subject in his original memoir; but when thanking Prof. Tyndall for a copy of that paper, some years ago, I myself took occasion to remark to him (as he may possibly recollect) that his results afforded a probable explanation of one of the uses of the odours of flowers, &c. Indeed, the probable connection, as pointed out by myself, and now by Mr. Olley, is so obvious that it can scarcely be missed. Still in this, as in most other cases, we have to ask of Nature the question "how much" before we can convert speculation into truth.

An atmosphere saturated in an odorous vapour is very different from the infinitesimally small and unweighable amount that is sufficient to diffuse the perfume of the flower or fruit, and in such minute proportions the "jacketing" effects, with wind freely blowing around, may be also all but evanescent,

Strong as is the odour of the lemon or orange when the rind is pressed or broken, those who have been in the orange orchards of the South may remember how the odour of the fruit rind is scarcely perceptible, unless when these are by any cause rubbed or struck against each other.—I am, &c.,

ROBERT MALLET.

November 8, 1872.

NEW PROCESSES FOR ANALYSING ETHERS.

To the Editor of the Chemical News.

SIR,—If Dr. Dupré will read Berthelot's "Chimie Organique fondée sur Synthèse," he will find that, before the year 1867, that chemist had analysed a compound ether by weighing the alcohol obtained from it.—I am, &c.,

J. ALFRED WANKLYN.

MISCELLANEOUS.

Report on the Condition of the Water Supply to London.—The official reports on the water supply to London are not satisfactory, by reason of the invalidity of the process of analysis adopted by the chemist to whom the Registrar General has confided the drawing up of the reports. As is well known the analyses in question are made by performing an organic analysis on the dry residue left on evaporating the water to dryness, whilst, as is now pretty generally understood, the extreme minuteness of the proportion of organic matter in drinking water, its proneness to change during the evaporation, and the difficulties entailed by the existence of comparatively large quantities of nitrates in drinking water, render the analysis very difficult and inaccurate. So inaccurate is it, that it is altogether illusory. But, although the English Government is employing a defective method for the performance of national work, there is a valid and practicable method known to science—that method is the now well-known ammonia-process, the joint invention of the late Mr. Chapman, Mr. Miles H. Smith, and myself. Almost every authority on the subject of water analysis has declared in favour of the latter process, and with greater or less distinctness against the former. In order to give some idea of this unanimity of the support given to the ammonia-process, it may be mentioned that Mr. Way, who was predecessor to the present Government chemist; the late Dr. W. Allen Miller, who did the water analysis for the Privy Council; Dr. Angus Smith; and Dr. Letheby have declared for it. In this country when Government neglects its duties private enterprise sometimes tries to discharge them. The following, which is the first of a series of monthly analyses of the London waters, is intended as a substitute for the analysis published by the Registrar General.

Thames Companies.	Parts in a Million. (Milligrammes per Litre.)

J. ALFRED WANKLYN.

CHEMICAL NOTICES FROM FOREIGN
SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 4, 1872.

In addition to a large number of original papers and memoirs relating to astronomy, meteorology, mathematics, natural history, geology, and comparative anatomy, this number contains the following original papers and memoirs relating to chemistry:—

Production of Alcohol by Fruit.—Professor Pasteur.—The author states that, as far back as the year 1869, Professors Lechartier and Bellamy made similar experiments to those referred to by him at the meeting of the Academy on October 7, respecting the formation of alcohol in fruit, and on the gases given off by fruit during its period of ripening; the results obtained agree in the main points with those obtained by Professor Pasteur, who, however, calls attention to the fact that his method differs essentially from that employed by the other authors, and that this is the cause of some of the discrepancies of the results.

New Discussion on Fermentation.—Professor Pasteur.—The author says that he placed in narrow tubes some juice obtained by simply squeezing grapes; this small quantity of juice could not possibly, at least according to Professor Fremy's opinion, have entered into fermentation under the conditions named, yet within twenty-four hours a vigorous fermentation had set in, and yeast was produced as usual, thereby proving that the objections made by Professor Fremy are not well founded. This communication gave rise to a reply by Professor Fremy, and Professor Pasteur afterwards requested the appointment of a committee of inquiry. Professor Dumas observed that for the purpose of verifying experiments a committee could be appointed, but not for appreciating scientific doctrines, and, as no doubt was thrown on the rigorous accuracy of Professor Pasteur's experiments, a committee was not required. Professor Fremy replied again, but the President, fearing that the discussion might become interminable, postponed the subject till next session.

Researches on Crystalline Dissociation; New Method for Studying the Coercive Action of Water upon Salts at Divers Temperatures.—P. A. Favre and C. A. Valson.—The continuation of a monograph on this subject.

New Process for the Mediate Analysis of Rocks, and Application of that Process to the Lava Obtained from the Latest Eruption of Santorin.—F. Fouqué.—This essay treats on the mechanical and chemical means employed for separating the different crystalline and amorphous constituents from rocks and minerals. The author recommends the use of concentrated hydrofluoric acid on the one hand, and electro-magnetic power on the other; he describes the application of his process to the lava referred to above.

Action of a Couple of Copper-Cadmium Plates upon a Solution of Sulphate of Cadmium.—F. Raoult.—Into a slightly acidulated solution of sulphate of cadmium, freed from air, are placed two small strips of sheet-copper and of sheet-cadmium, both being entirely immersed in the fluid and not touching each other, care being taken to prevent access of air by pouring some oil on to the surface of the liquid. As long as the two metals are not in contact, nothing particular is observed; but as soon as a suitable motion is given to the vessel in which the fluids and metals are placed, and contact is thereby established between the two metals, cadmium is reduced and deposited upon the copper.

The Anti-Fermentation Property of Silicate of Soda.—M. Picot.—After first briefly referring to the researches of Rabuteau and Papillon on this subject, the author describes at length the results of a series of experiments, from which it appears that, even in small quantity, silicate of soda exerts a powerful effect—of either entirely arresting, or greatly reducing in activity, the alcoholic and the lactic, as well as the putrid, fermentation.

Le Moniteur Scientifique Queneville, No. 371, November, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

On Pulmonary Respiration and on Animal Heat.—Ch. Blondeau.—The end of an exhaustive monograph on this subject.

Mustard Studied Therapeutically, and its Applications to Practical Medicine.—Dr. H. Astier.—By pressure mustard-seed yields a fixed oil analogous to colza oil, and, in addition, the seed contains albumen, sugar, gum, colouring matter, a green-coloured substance, sinapisin in small quantity, a free acid, some salts (more especially those of potassa), and, lastly, myrosine and myronate of potassa, by the mutual reaction of which, under the influence of water,

the essential oil of mustard, or sulphocyanide of allyl, is formed. Myrosine is soluble in water, is coagulable by heat, alcohol, and acids, and is best extracted from white mustard-seed by exhausting it first with cold water, and evaporating this fluid at a temperature not exceeding 40° to the consistency of a syrup, from which the myrosine is precipitated by alcohol. The myronate of potassa is extracted from black mustard-seed (the white only contains a trace), which is first deprived of its fixed oil by strong pressure or by the aid of sulphide of carbon. The residue is next treated with alcohol at 85 per cent heated to about 60°, for the purpose of eliminating such substances as would interfere with the crystallisation of the myronate of potassa. The residue is next treated with tepid water, which dissolves the myronate of potassa; the liquor thus obtained is evaporated to the consistency of a syrup, and then treated with weak alcohol for the purpose of precipitating mucilaginous matters, after which the fluid is concentrated by evaporation, and left to crystallise. The myronate of potassa is, lastly, washed with weak alcohol, yielding perfectly colourless crystals. If it is desired to separate the myronic acid (for it is that substance which, with myrosine, yields, by contact with water, the essential oil of mustard, or sulphocyanide of allyl)—

the myronate of potassa is dissolved in water, and mixed with a solution of tartaric acid, then filtered, concentrated by evaporation, and next treated with alcohol; myronic acid can only be obtained as a syrup-like fluid, of an acid taste, but without smell. The pure essential oil of mustard, or sulphocyanide of allyl, is a colourless oily liquid, boiling at 143°, slightly soluble in water, but in every proportion in alcohol and ether; with ammonia it yields a crystalline compound, thiosinamine, $(C_8H_7N_2S_2)$. White mustard-seed contains sinapisin or sinapine, $(C_{22}H_{34}O_{10})$, combined with hydrosulphocyanic acid. This essay also contains valuable information on the best modes of applying mustard therapeutically.

Intérometer.—A. Joulet.—The description, elucidated by woodcuts, of an ingeniously-contrived instrument, invented by Deprez and Collignon, for the purpose of facilitating, and even superseding, geometrical calculations.

Non-Freezing Public Fountain.—MM. Broquin and Lainé.—The detailed description, elucidated by engravings, of a well-arranged mechanism to prevent public fountains, not uninterruptedly flowing, from freezing and consequent bursting of pipes.

Compression of Air and of Gases.—M. Colladon.—The account of an apparatus by the aid of which air or gases may be strongly compressed, while, at the same time, the necessary arrangement is made to cool the gases without the necessity of introducing water into the force-pumps. It appears that, notwithstanding the somewhat complicated construction of the machinery, it is effective and not liable to become readily disabled by use.

Annalen der Physik und Chemie, von Dr. J. C. Poggendorff, No. 10 1872.

This number contains the following original essays and papers relating to chemistry and collateral sciences:—

Behaviour during Expansion of Superheated Vapours.—Dr. H. Herwig.—An algebraico-physical essay.

Osmotic (Diosmotische) Researches.—J. Baranetzky.—This monograph, illustrated by engravings, treats of the phenomena of endosmose, exosmose, diffusion, and osmose.

Mineralogical Communications.—G. vom Rath.—The last portion of a paper on this subject, treating of humite, of leucite expelled from Vesuvius, of a mineral like cyanite met with in the basalt on the banks of the Rhine, and of two soda-lime felspars from the Ural.

Contributions to Micro-Mineralogy.—Dr. von Lasaulx.—The conclusion of the author's monograph on this subject, illustrated by engravings.

Polytechnisches Journal von Dr. E. M. Döngler, first number for October, 1872.

This number contains the following original papers and essays relating to chemistry and collateral subjects:—

Manufacture of Dynamite.—F. Capitaine.—This essay details the preparation of dynamite as carried on industrially with a yield of 5 tons a day. The preparation of the nitro-glycerine is conducted by the safest operations possible.

Estimation of the Quantity of Pure Sugar Contained in Various Kinds of Raw Beet-Root Sugar.—Dr. E. Scheibler.—This essay, illustrated by engravings of the apparatus, contains the description of a method of sugar estimation which is a modification of Payen's plan of treating the raw sugar with a mixture of strong alcohol and concentrated acetic acid.

Industrial Preparation of Blood- and Egg-Albumen.—E. Campe.—This essay treats exhaustively of the preparation of the large quantities of dried albumen required by calico-printers.

Dyeing of Furs.—F. F. Keferstein.

Portable Odourless Earth-Closet.—E. Cohn.—Illustrated by a woodcut; the arrangement is very similar to one of the closets patented by Mr. Bostel, of Brighton.

Constituents of Tobacco Smoke.—Eulenburg and Vohl.—Tobacco smoke does not contain, as is often supposed, nicotine; but the authors found ammonia, pyridine, picoline, lutidine, collidine, formic, acetic, propionic, butyric, valeric, and carbonic acids, and creosote (Reichenbach's).

Journal für Praktische Chemie, No. 13, 1872.

This number contains the following original papers and memoirs:—
Some New Organic Compounds, and on New Means of Preparing the same.—Dr. F. Plankuch.—This essay, divided into three main sections, treats on cyanoform and methin-tricarboic acid. The preparation of the mercurio-iodide of cyanoform is first described at great length; this compound is soluble in ether and in alcohol, and also combines with iodide of ammonium, the mercury being eliminated; the formula of the mercury combination is $C_3H_2N_4HgI_2$. Cyanoform has not been isolated, but, by treating one of its combinations with caustic soda, methin-tricarboic acid is formed; this is a strong acid, readily combining with bases, and yielding with them crystallisable salts; the formula of this acid is $C_3H_2O_6$, and it is in free state a solid crystalline compound, soluble in ether. The second part of this paper treats exhaustively on a new method of preparing, by a complicated process, hydrocarbons; and the third section treats on some new reactions of sulphur, chiefly based upon the strong affinity for oxygen which sulphur exhibits at a high temperature, also when in contact with organic bodies.

Cyancarbonic Acid Ether.—A. Weddige.—This substance is prepared by the reaction of phosphoric anhydride upon oxamethan. The ether is a clear, limpid, mobile fluid, boiling at between 115° and 116° ; it is insoluble in water, but, when left for a long time in contact with it, the ether is decomposed, with the formation of hydrocyanic acid, carbonic acid, and alcohol; the formula of this ether is—

Method for the Quantitative Estimation of Asparagine.—Dr. R. Sachsse.—An essay of great scientific value, but not suited for abstraction.

Action of the Hydrogen Occluded in Palladium upon some Organic Compounds.—Dr. M. Saytzeff.—This monograph, illustrated by woodcuts, is divided into the following sections:—Introduction, recording a *resumé* of the labours of the late Professor Graham, of Drs. Kolbe, Böttcher, and others; action of the hydrogen absorbed by palladium upon benzoyl chloride, upon nitro-benzol, nitro-phenol, and nitro-carbol.

Some Derivatives of Mucic Acid.—M. Kötnitz.—This essay, of which only a portion is here published, treats on mucate of aniline, $C_6H_5O_8(C_6H_5H_2N)_2$, a crystalline compound, soluble in water, but insoluble in alcohol, decomposed by alkalis, aniline being set free, and mucate of the base formed. The author further treats at length on the behaviour of mucate of aniline when boiled for a long time, whereby an impure compound only is obtained, and next on the behaviour of mucate of aniline when heated in an air-bath, whereby anilide of mucic acid is formed, the formula of that compound being—

Neues Jahrbuch für Pharmacie und Verwandte Fächer, von Dr. F. Vorwerk, September, 1872.

In addition to papers particularly relating to pharmacy, this number contains the following original papers relating to chemistry:—

Contribution to our Knowledge of Gum Arabic.—Dr. Graeger. After a reference to Fremy's researches, the author treats on metagummic acid—premising that the gum arabic of commerce is essentially a salt, and chiefly a lime salt of this acid—which is an amorphous, rather hygroscopic, compound, colourless and tasteless, in moist state it exhibits a decidedly acid reaction, and is insoluble in pure water, but readily soluble in very dilute alkaline fluids; formula, $C_6H_5O_7$. By treatment first with lime-water, and next with oxalic acid, gummic acid is formed, which is an amorphous compound, soluble in water, and strongly acid.

On Hydrocyanates of Alkaloids.—F. A. Flückiger.—From the researches here recorded it appears that the hydrocyanates of berberine, morphine, cinchonine, and strychnine, do not exist, since the compounds taken to be combinations of these alkaloids and hydrocyanic acid are simply the free alkaloids.

Chemical Investigation of German and other Wines.—G. Gläser.—The author exhibits the quantity by weight per cent of alcohol, of grape sugar, of free acid, of extract, and of mineral matter, contained in a number of various samples of wine.

Detection of Water and of Alcohol in Ether.—R. Böttger.—To 10 c.c. of the ether to be tested add an equal bulk of pure sulphide of carbon, and shake the mixture; if the ether is anhydrous, a perfectly homogeneous fluid will be obtained, but, when the least trace of water is present in the ether, the mixed fluids exhibit a milky appearance; when the ether contains alcohol, a piece of dry caustic potassa, left in contact with the ether for twenty-four hours, will become coated with a yellowish-coloured matter.

Les Mondes, October 31, 1872.

Curious Experiment.—Rev. Father Lafond, S.J.—Take a chameleon-top, and place on the centre one of the discs sold with that toy; then, instead of obtaining the optical illusions produced by touching the surface of the spinning top with a pointed instrument (checked motion of Wheatstone), place on the table a large Geissler tube, and the result of this illumination will be the exhibition of the most varied and charming colours and designs, without the necessity of touching the

disc placed on the spinning top. This experiment also proves that the light given off by the Geissler tubes is *intermittent*.

Taupe Marine.—G. Toselli.—The author has made an improved machine of this description; it is a kind of diving-bell, and is destined for coral-fishing purposes on the Sardinian coasts. This machine, weighing 4 tons, and constructed at Paris, will be first tried in the Mediterranean off Marseilles; by its aid depths to which divers would never be able to descend can be explored, and the men can remain under water for a whole day if required with safety and without any inconvenience.

Manure for Horticultural Use.—Dr. Jeannel.—This is made as follows:—Nitrate of ammonia, 403 parts; biphosphate of ammonia, 200; nitrate of potassa, 250; chloride of ammonium, 50; sulphate of lime, 60; sulphate of iron, 40. These ingredients are pulverised, well mixed, and kept in well-closed dry bottles. 4 grms. of this mixture are dissolved in 1 litre of water, and to each plant (in pots or in open ground) is given weekly a dose of from 25 to 50 or, even in some cases, 100 grms. It is best to pour the liquid in the saucers in which the pots are placed.

Method of Measuring the Velocity of Light with more Precision.—L'Abbé Laborde.—An optical essay, illustrated by a woodcut.

November 7, 1872.

Inauguration of the New Observatory at Florence.—C. Flammarion.—On the hill of Arcetri, the scene of the labours of Galileo Gallilei during the later years of his life, has been constructed a well-arranged observatory, under the care of Donati. This scientific establishment has just been inaugurated in the presence of a number of distinguished men, worthy representatives of a nation which follows the steps of those illustrious *savants* whose labours have rendered Italy, and especially Florence, renowned in the annals of science.

Atmospheric Postal Communication between England and France.—E. Martin.—In a letter to the Editor, the author suggests the plan of laying down between Cape Gris-Nez and Shakespeare Cliff, Dover (a distance of 29 kilometres), a series of iron tubes similar to those already in use in London and Paris for the conveyance of mails by atmospheric pressure.

Taupe Marine.—J. B. Toselli.—The detailed illustrated description of this ingeniously-contrived machine, which will be found to supersede anything of the kind hitherto invented for executing with perfect ease and safety work under water.

Petites Annales de Chimie.—E. J. Maumené.—The eighth portion of this monograph.

La Revue Scientifique de la France et de l'Etranger,
November 2, 1872.

This number contains no original papers relating to chemistry, but we quote the titles of the following memoirs:—

Biography of the Late Professor Babinet.—E. Alglave.

Scientific Instruments and Implements Required by Military Officers in Field Duty.—A. Lausedat.—An illustrated description of physical instruments which may also be of service for general scientific purposes.

November 9, 1872.

This number contains no original papers relating to chemistry, but we call attention to the following memoir:—

Phenomena of Life Common to Plants as well as Animals.—Dr. C. Bernard.—This essay, the concluding portion of the author's lectures on general physiology, is divided into the following sections:—Identity of animal glucogen and vegetable starch in a physiological point of view; origin and formation of glucose in animals and plants; conditions which influence the glucogenesis.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents,
54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2711. W. D. Ruck, Greenwich, Kent, "Improvements in the manufacture of gas."—Petition recorded September 12, 1872.

2988. J. Young, Kelly, Renfrewshire, N.B., "Improvements in treating liquors containing amfetronical compounds in order to obtain products therefrom."—Petition recorded October 10, 1872.

3056. A. V. Newton, Chancery Lane, Middlesex, "An improvement in the manufacture of iron and steel wire."—A communication from D. H. Rump, Altena, Westphalia, Prussia.—Petition recorded October 16, 1872.

3101. W. R. Lake, Southampton Buildings, London, "Improved processes and apparatus for manufacturing compounds of pyroxyline or gun-cotton."—A communication from J. W. Hyatt and J. S. Hyatt, Albany, New York, U.S.A.

3103. R. F. Fairlie, Victoria Street, Westminster, "Improvements in apparatus for the extraction of nitrate of soda from crude nitrate earth-stone, usually called *calèche*."—Petitions recorded October 21, 1872.

3142. A. V. Newton, Chancery Lane, Middlesex, "Improvements in furnaces for burning sulphurous ores."—A communication from K. Walter, Augsburg, Bavaria.—Petition recorded October 23, 1872.
3163. A. Allison, Bayswater, Middlesex, "Improved means of preserving and curing raw meat, in packing the same, and in apparatus employed therewith."
3173. E. Rowe, Brentwood, Essex, "Improvements in treating earths or materials containing metallic oxides, and in obtaining products therefrom, and in the use of such products."—Petitions recorded October 25, 1872.
3180. A. Malam, Dumfries, N.B., "Improvements in the manufacture of illuminating gas, and in apparatus therefor."—Petition recorded October 26, 1872.
3192. E. P. H. Vaughan, F.C.S., Chancery Lane, Middlesex, "Improvements in the mode of, and apparatus for, generating gas for lighting and heating purposes."—A communication from E. A. Dubois, Paris.—October 28, 1872.

95757. Sinclair, "Improvements in the treatment of spent lye of wood pulp."

NOTES AND QUERIES.

Bleaching Shellac.—Can you inform me of a practical process for bleaching shellac to make colourless French polish, or for dissolving the bleached lac of commerce in alcohol for the same end? All the white lac I have ever been able to try has appeared absolutely insoluble, and I have been informed that it is necessary to dissolve the lac immediately after bleaching, as it afterwards becomes insoluble.—Lac INSECT.

[Dissolve the lac first in a boiling lye of caustic potassa or soda, and next pass chlorine through the solution until all the lac is precipitated; this is collected, washed, and pulled in hot water, twisted into sticks, and finally thrown into cold water. The bleached shellac, if properly prepared, dissolves perfectly in methylated spirits, but it requires more of that fluid for solution than the unbleached lac, and the solution requires the aid of heat].

Chemical Technology, or Chemistry in its

Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The LABORATORY will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

Royal Polytechnic.—Open at 12 and 7. Admission 1s. New Ghost, THE WHITE LADY OF AVENEL.—THE SLEEPING BEAUTY, by Mr. George Buckland, assisted by Misses Alice Barth and Florence Hunter.—COAL, & HOW TO SAVE IT, by Professor Gardner.—Lectures on Natural Philosophy, by Mr. King; the Diver and Diving Bell; and many other Entertainments.

THE CHEMICAL NEWS.

VOL. XXVI. No. 678.

ON THE LOSS THROUGH VOLATILISATION IN THE CORNISH COPPER ASSAY.

By CORNELIUS A. MAHONY.

ALL the copper ores sold in the English market have their produce determined by the dry Cornish assay, a method which, while it gives concordant results (the limit of error being $\frac{1}{2}$ per cent), always fails to indicate the true amount of metal contained in the sample, owing almost entirely to the fact that copper is sensibly volatile in the presence of sodium chloride, a substance largely used in the assay.

There are three distinct stages in the assay, viz.—

1. Fusion for regulus.
2. Calcination of regulus.
3. Refining of regulus.

The first operation has for its object the production of a regulus, or matt, containing all the copper, together with iron, sulphur, and traces of other metals. To effect this the ore is mixed with a flux, composed of lime, fluor-spar, borax, and salt, together with a definite quantity of nitre. As the salt is without action on the metallic sulphides formed, its use here is not open to objection.

In the second operation the sulphides are carefully roasted, to expel the sulphur (after having been first ground very fine), and any loss that may seem must necessarily be in manipulation.

The third stage, and the one in which the error of copper almost entirely takes place, is the fusion for coarse copper and refining. The oxides produced in the last operation are reduced at a high temperature, in the presence of argol, nitre, borax, and salt (about 100 grains of the latter being used), and the crude button of metal obtained is again subject to fusion with "refining flux," composed of equal parts tartar and nitre one ladle, and salt one ladle. One ladle about 5 dwts. This fusion is repeated three or four times if required, until the button presents the appearance of "fine copper." The slags from all the fusions are then reduced with a small ladle of argol, when a "prill," or little globule of copper more or less impregnated with iron, is obtained, which is weighed, together with the large button, and the percentage expressed to eighths.

The usual time the button is exposed to the furnace heat, in refining, is from 3 to 5 minutes; and in order to have data for the amount of volatilisation likely to occur during such exposure, the following experiment was resorted to, viz. :—

A button of pure copper was subject to four several fusions with sodium chloride, and carefully weighed after each, the heat of the assay furnace being that necessary in the refining operation. The button operated on weighed 49.51 grs., and 240 grs. of salt were used at each fusion. The loss of weight was as follows:—0.33, 0.34, 0.21, and 0.42 grs. respectively, giving an average of 0.32 grs. of loss for 5 minutes' fusion. The slag contained a mere trace of copper.

Another button, weighing 48.32 grs., lost 0.31, 0.33, and 0.32 grs. in three several fusions, with 480 grs. sodium chloride.

To ascertain the loss actually sustained through volatilisation, in the dry assay, three samples were assayed, the button of copper obtained weighed, and the small percentage left in the slag carefully estimated by wet process, and its weight added to that of the large button. The difference between the percentage thus formed and the total percentage of copper in the sample determined

in the wet way, by titrating with standard potassic cyanide, was put down as loss through volatilisation.

No.	Per-centage from Button.	Per-centage in Slag.	Total per-centage.	Per-centage by Wet Assay.	Loss = difference of — D.	Description of Sample.
1.	10.12	0.07	10.19	11.25	1.06	Copper pyrites.
2.	8.88	0.12	9.00	10.20	1.20	" "
3.	13.88	0.27	14.15	15.00	0.85	" "

It would appear that, by making as few fusions as possible in the refining process, the loss might be diminished, but, on the other hand, it would then become necessary to procure a very fine regulus, and we would run the danger of allowing copper to pass into the slag of our first operation.

I would suggest to metallurgical chemists the desirability of devising a substitute for sodium chloride, and thus giving to this assay something approaching to analytical accuracy. Experiments made with glass of borax have resulted in failure; neither are the alkaline carbonates suitable; yet I believe that it may be feasible to devise a flux in the presence of which copper will not be so volatile, and thus remove the *bête noir* of the Cornish copper assay.

THE CHEMICAL PROCESS OF RESPIRATION CONSIDERED AS A PHENOMENON OF DISSOCIATION.

By F. C. DONDERS, M.D., &c.,
Professor in the Medical Faculty of Utrecht University.

FOR the ancient chemical theories of respiration a mechanical one, first established by Magnus, has been substituted. The idea upon which this theory is based is a physical exchange of the gases dissolved in the blood, and those of the air which fills the lungs. A kind of diffusion therefore takes place; but this theory was not found to hold good without the aid of what have been termed instable, lax, chemical combinations, and facts were successively discovered which indicated a real chemical action. So long as the gases could be either chased away into a vacuum or expelled by the aid of other gases one had to deal (unless it were a simple case of solution) with a lax (*lache*) chemical combination; but when the gases were so fixed that these means no longer sufficed for their expulsion, there could be no more question of a true chemical combination, in *optima forma*, being certainly at work. It is in this manner, as proved by Pflüger, that the blood drawn from a vein fixes in a few minutes a certain quantity of oxygen, and an analogous chemical action takes place in the interior of the capillary vessels of the great circulation, as well as in their immediate neighbourhood. It is by another chemical action that the lungs actively promote the expulsion of CO₂ (Ludwig). But I do not here wish to allude further to the above-mentioned phenomena, which, moreover, are already beyond the proper notion of the chemical process of respiration.

I intend to confine myself to the reversible actions,—the expulsion for an unlimited number of times of O by CO₂ and of CO₂ by O, of which Magnus's experiments have given us a clear idea,—actions which, leaving solution out of the question, have been referred to "lax" chemical combinations: in other words, I shall treat on the condition of the exchange of gases, in the form in which it takes place with given gases, without taking into consideration what precedes or follows; for it is within these limits that, according to my opinion, the chemical process of respiration has to be interpreted as a phenomenon of dissociation. These lax combinations are in a state of dissociation, *partly* entire, *partly* destroyed.

Dissociation is either the resolution (*résolution*) of the molecule of a body into two or more molecules of a new

and less complex combination, either similar or dissimilar to each other—

or the reaction of one molecule upon another, thus giving rise to the formation of new molecules by double decomposition ($H_2O + H_2O = 2(H_2 + O_2)$). The characteristic of dissociation is, that the phenomena are brought about *under the influence of a certain temperature*, without the intervention of any other body. This is the definition of dissociation in the widest sense of the word, but in a more restricted sense it comprehends the phenomena before mentioned only when the action is reversible in such a manner that the molecules, into which the body is split up by the heat, re-unite to form the primitive combination as soon as the primitive conditions of temperature and tension which previously existed are re-established. Such reversible actions are apparent in the two instances I have cited.

As instances of non-reversible actions we may quote the dissociation of ammonia into nitrogen and hydrogen ($NH_3 + NH_3 = N_2 + 3H_2$), and also the decomposition, by heat, of sugar, albuminoid matter, &c. In the reversible actions we have to deal both with the mobile equilibrium of the molecules, on which much light has been thrown by Drs. Buys-Ballot and Pfauñler, and also with the *chemismus* (*chimisme*) of the respiration.

A compound is in the condition of dissociation when, under the influence of a constant temperature, it is partly decomposed, while another portion of the same compound remains unaltered. This partial decomposition is most readily observed when the body undergoing dissociation is itself fixed, while one or more of its products of decomposition has assumed the gaseous condition. Carbonate of lime is a good example of this, for, as proved by Debray, this substance heated in vacuum up to 350° ; a scarcely perceptible decomposition took place at 440° (temperature of dissociation); at 860° the decomposition continued, so that the pressure of the carbonic acid set free was equal to 85 m.m.; while at 1060° this pressure attained 520 m.m. The condition of equilibrium for a given temperature is attained when the density of the CO_2 gas is such that the number of outgoing molecules is equal to the number of ingoing molecules (mobile equilibrium of the molecules). When the outgoing molecules are gradually carried off, by an atmosphere free from carbonic acid, so that no more molecules can enter, the decomposition becomes complete, provided always that the temperature of dissociation be attained, and that decomposition proceeds more rapidly the higher the temperature. A solution of bicarbonate of potassa charged with an excess of crystals of that salt, and placed in a vacuum, also loses carbonic acid in the same manner, until that gas in free state exerts a determined pressure, which increases with the temperature. Even at the ordinary temperature this salt and also the bicarbonate of soda are completely converted into neutral carbonates, when the products CO_2 and H_2O are gradually carried off while being evolved,—an operation which takes place even at 10° , while of course at a higher temperature the operation of conversion into neutral carbonate goes on more rapidly. In the reversible process the dissociation is accompanied by an absorption of heat, while, by the re-combination, an evolution of heat takes place.

The definition just given of the phenomenon of dissociation is sufficient to prove that it plays an essential part in the exchange of gaseous matter which takes place in the blood: it is rather curious that this has not been already recognised and made generally known,—the more so since all the facts known concerning absorption, the displacement (*déplacement*), and extraction of the gases from blood, concur with this view. We here come in contact with substances which are in the condition of dissociation at the ordinary temperature: there, where the quantities agree with Dalton's law, we admit ordinary solution, such as undoubtedly takes place with nitrogen.

In several salts, and probably also in some of the albuminoid matters present in the plasma of the blood, as well as in the blood corpuscles, we find these bodies in a condition of dissociation, so that they yield CO_2 , in the presence of the tension of CO_2 , such as it exists in the lungs, which absorb it according to the degree of tension it has in the tissues, this action being dependent upon the limits of the temperature by which it is, to a certain extent, regulated.

As regards oxygen, the oxyhæmoglobine is the body in a state of dissociation, since it absorbs O under the degree of pressure of that gas in the lungs, and gives it off again under the conditions of pressure of that gas which obtains in the tissues, either action being undoubtedly aided by the intermediate of the blood plasma, which, as regards O, behaves rather as a simple solvent.

According to this view it is necessary that the determinations which are in general required for bodies in the state of dissociation be made for blood, and for some of its constituents; thus the determination of the temperature at which the dissociation begins, that of the degree of dissociation in reference to the tension and to the temperature, and also the degree of rapidity with which the dissociation proceeds.

It is clear that many important questions concerning the molecular renovation (*renovation moléculaire*) in warm- and cold-blooded animals, in normal and abnormal conditions, are bound up with these determinations. In some of the researches made by me on this subject, I have also noticed the combination of the oxide of carbon with the hæmoglobine of the blood-corpuscles; but I have up to the present time chiefly studied the influence of the temperature on the phenomena of dissociation, and the following results have been obtained:—

I. Defibrinated blood having been shaken to saturation with atmospheric air previously freed from CO_2 , oxygen was expelled from the blood.

(a). By H at 0° , temperature of dissociation being barely attained; at 1° , dissociation unquestionable, although very weak; at 37° , the current of H drives off more oxygen in 10 seconds of time than at 1° in 1000 seconds.

(b). By CO_2 , it is found that at 37° O is expelled more rapidly than at 0° , although at 0° more O is probably absorbed. Even at 0° the samples of blood operated upon are rendered of a dark colour in a few seconds of time; and in this respect CO_2 acts far more rapidly than H. It should be observed that the samples submitted to the action of CO_2 do not become darker coloured till after 1 or 2 days, but even then the colour is brighter than that exhibited by the samples only treated with air, deprived of CO_2 without further treatment to a current of CO_2 . At the end of two and a half days all the samples exhibit the same colour; hence it follows that the decrease of O and absorption of CO_2 prevents the ulterior transformation of the blood. It appears that CO_2 generally has a depressing effect upon the chemical actions of which it is itself one of the products. From this point of view it is explainable that the presence of CO_2 and the decrease of the quantity of O are both in the same manner, viz., by slackening the speed of the molecular exchange, the indirect active stimulant of the respiratory motion. When a current of CO_2 is passed through blood at a higher temperature, the result is that after a certain time the hæmoglobine becomes slightly decomposed, and consequently the experiments are not to be relied upon.

II. Defibrinated blood, first treated with CO_2 in excess and next submitted to the action of a current of atmospheric air completely free from CO_2 , becomes of a bright red colour far more rapidly at 0° than at 37° . At 0° the bright colour was more developed in half a second than at 37° after the lapse of one minute. After the passage of the air had been continued through both samples for six minutes of time, they were equally and identically bright in colour. At 0° , the blood through which air was passed, formed, *ceteris paribus* (*toutes conditions égales d'ailleurs*), bubbles exhibiting a larger surface. This circumstance in

Experiment I. exerted an unfavourable influence on the evolution of O; in Experiment II. a favourable influence on its absorption. Consequently the result of I. is, *a fortiori*, true, and more fully proved than that of II.; in respect of which, new experiments conducted in a different manner will be necessary.

III. Defibrinated blood, first saturated with oxide of carbon submitted to a current of O, of H, or of CO₂, loses its oxide of carbon already at 0°, so that the hæmoglobine is more and more freed of its CO. The assertion of Hermann that O is driven out from its combinations with hæmoglobine by CO, but that a reciprocal action does not take place is not true; even H expels CO, and even at 0° the CO hæmoglobine is in a state of dissociation. Temperature plays a great part in the expulsion by H; while as regards expulsion by O, the influence of the temperature is very slight. Under the influence of a current of O CO is not expelled in the condition of CO₂. When every trace of CO₂ has been expelled from blood by means of CO, and the blood next submitted to the action of a current of air previously freed completely from carbonic acid, it does not yield even at 37° any appreciable quantity of CO₂ while the experiment is continued for a whole hour; during which time a great part of the CO-hæmoglobine is converted into oxy-hæmoglobine. In my first experiments, sufficient care had not been taken about the complete expulsion of the gas CO quite free from CO₂, and I had found traces of CO₂ in the air after it had passed through the blood. CO₂ drives out CO more rapidly at 37° and at 40° than at 0°; but this action also causes the decomposition of the hæmoglobine, and renders the blood brown coloured. It remains to be proved whether in the—according to Hermann—far more stable combination of hæmoglobine with oxide of nitrogen the temperature of dissociation is also attained at 0°.

IV. Paraglobuline, precipitated by CO₂ in dilute serum, is red; it is dissolved as well by the influence of H (first discovered by Dr. Heynsius) as by that of O, but in the latter case the solution is more complete, while it is far more rapidly effected at 37° than at 0°. It is probable that paraglobuline is a combination—soluble in the salts (serum)—of globuline and carbonic acid, a combination which is in a condition of dissociation at the ordinary temperature. The experimental demonstration of the hypothesis that paraglobuline is CO₂-globuline is confronted with the difficulty of obtaining paraglobuline in water completely freed from CO₂. Freshly-prepared fibrine evolves CO₂. After all the CO₂ has been expelled by a rapid and abundant current of H, traces of CO₂ are again given off for several hours, and even days, under the influence of a slow current of H; it is possible that in this case also dissociation plays a part.

The above mentioned results were communicated by me to the Academy of Sciences at Amsterdam, at a meeting in January, 1871; when I also treated on the phenomena of gaseous exchange which take place in the lungs, and in the organism within the blood as well as beyond it. Some weeks previously my learned friend Dr. Ludwig had presented to the Royal Saxon Society of Sciences (at a meeting on the 12th December, 1870) a memoir by J. W. Müller, "On the Tension of Oxygen in the Blood Corpuscles." This memoir, which has since been published, contains the record of two series of experiments made with great care and perseverance. (a). Blood poor in O was shaken up in a closed vessel with a known quantity of O. (b). Blood rich in O was shaken up in a closed vessel with a known quantity of N; and after equilibrium had been apparently obtained, the tension of O beyond the blood was compared with the proportion of O in the blood. The results would certainly have been more interesting if the method of experiment had admitted of the disposition of any desired temperature. Moreover, it was found that a complete equilibrium had not been obtained, because, when the O from the blood (b) was expelled, the proportion of O in that liquid compared with the tension beyond was far greater than at the time of the absorption of O (a). These experiments,

however, bear directly on the important question to be solved, and they should be resumed, but with still smaller quantities of O, because even with 20 m.m. pressure of O saturation is nearly attained after a prolonged agitation; and it would hence appear that the equilibrium has been more completely reached in the series (a) than in (b). The exchange of gases in the blood is referred by Müller as well as myself to dissociation: and while Dr. Ludwig also adopts this view he states that it is not the oxygen which penetrates into the tissues, but that, on the contrary, the products of the decomposition of the tissues enter the blood to be completely oxidised therein. When I publish a full account of my experiments I shall again revert to this important point.

I will bring this essay to a close with a word on the difference existing between solution and chemical combination. I have called attention to the experiments of Debray on the dissociation of CaCO₃, by which he determined for different temperatures the tension of CO₂ corresponding to the mobile equilibrium. If the temperature continued to increase we might imagine, provided always that no further dissociation of the molecules of CO₂ nor of CaO takes place, that we should finally come to a condition in which, in conformity with Dalton's law, a constant volume of CO₂ was dissolved in molten lime no matter under what pressure, just as H and N are dissolved in water. Indeed, thermo-chemistry teaches us that a combination at different temperatures passes through all conditions which at one and the same temperatures are exhibited by different bodies. In this way the marked separation existing between solution and chemical combination disappears. The experiments of Roscoe and Dittmar (1859) are, in this respect, of great interest, as by them it was found that, in respect to water, ammonia at 0° is far from obeying Dalton's law; and also with regard to the experiments of Sims, in which it was made out that this only takes place towards 100°; while, according to the same authority, sulphurous acid does not obey the law in question except at temperatures above 40° (above 50° according to the figures published). The deviations are most marked for feeble pressures. It is probable that at a very low temperature, and under very low pressure, even CO₂ will not perfectly obey Dalton's law as regards its solubility in water.—*Archives Néerland. d. Sciences.*

ON THE ACTION OF CHROMIUM TRIOXIDE ON IODINE.

By I. WALZ, Ph.D.

A CONCENTRATED solution of chromium trioxide, when poured on iodine, turns rapidly dark, and assumes a syrupy consistence. The liquid thus formed does not respond to any of the reactions of free iodic or hydriodic acid. Spread in thin layers on glass plates it dries, in dry air, to a reddish-brown transparent varnish, which may be taken off in bright shining scales, which are hygroscopic, lose their lustre at a higher temperature owing to the dehydration, and when heated still higher are decomposed, oxygen and iodine being evolved, and green chromium oxide being left behind. Among the products of this decomposition is a volatile compound, of chromium and iodine, which seems to be decomposed at a temperature but little above that at which it is formed: if the scales before mentioned are heated to decomposition in a covered porcelain crucible, the heat being applied from the cover downwards, the inside of the latter will be found coated with green chromium oxide, resulting from the decomposition of this compound, in the isolation of which I was, however, not successful. At first I took these scales for a new and definite compound of iodine and chromium trioxide; but the analyses of the products of different preparations gave no uniform results, and I found that they were a mixture of chromium, chromium subiodate, and water in varying proportions.

If a solution of chromium trioxide and sulphuric acid be allowed to act on iodine, oxidation soon takes place, iodic acid being formed whether iodine be present in excess or not. I observed, however, that in no instance was all the chromium trioxide reduced to sesquioxide: in one instance a large excess of iodine and sulphuric acid was used, the contents of the beaker kept on the water-bath for a week, and allowed to become very concentrated every time before water was again added, and yet some chromium trioxide escaped reduction. To obtain the iodic acid pure, chromium sesquioxide is precipitated by sodium hydrate, the filtered solutions neutralised with nitric acid, and sulphuric precipitated by means of barium nitrate. The resulting solution is neutralised with sodium hydrate and chromic acid, precipitated by adding baryta water. The resulting colourless liquid contains only sodium nitrate and iodate, and the presence of the latter may be demonstrated by the usual tests, or it may be separated from the nitrate in various ways. Of course this method is far too laborious to become practically useful, but I deemed the reaction itself, and the few points noted in connection with it, worth communicating, as it has not, to my knowledge, been studied before.—*American Chemist*.

WATER ANALYSIS IN INDIA.

We have received from Dr. Macnamara a reply to a paper by Mr. Nicholson, published in our issue of August 9th. The subject has already occupied considerable space in our columns. In justice, however, to Dr. Macnamara, we give the chief points of his reply to Mr. Nicholson's criticism; and here we deem it expedient to end the discussion, as in our opinion its continuance can be of no practical interest to our readers. In his reply Dr. Macnamara says:—

"When I went home on furlough in 1869, finding that the Bengal reports upon the analysis of potable waters had been officially referred to Dr. Angus Smith for criticism, and finding that that gentleman had already made suggestions as to the methods of analysis which should be followed, I asked that I might be officially placed in communication with him, with a view to the conjoint compilation of a scheme of analysis for general use in India. To this request the Secretary of State consented, and subsequently suggested that with reference to the compilation we should put ourselves in communication with Dr. Parkes; so that from the commencement I was joined in the compilation of this scheme with Dr. Angus Smith, whom I need scarcely say stands in the very first rank of English chemists, and with Dr. Parkes, who is pre-eminently qualified to form an opinion as to the scope of a scheme designed to be a guide to the analysis of potable waters for hygienic purposes.

"The scheme was compiled to be a guide to the examination of potable waters for hygienic purposes, not as a scheme for the minute and accurate analysis of waters generally; for indeed it is not needful to the determination of the fitness of a water for consumption to estimate in this way the whole of its constituents.

"Primarily the scheme was intended for the use of medical officers, who, having gone through the course of practical chemistry at Netley, might subsequently be called on to analyse potable waters in India; further, it was intended for use in the laboratory at Netley; and lastly, to aid professional chemists who might be employed in analysing waters in India,—not to direct them as to the details of the processes involved, but to indicate the nature and extent of the information which the Army Sanitary Commission, with whom this enquiry regarding potable waters originated, would require. Having these objects in view, the scheme is necessarily wanting in that homogeneity which one designed either for learners or for experienced chemists ought to possess. The scheme

would not have been compiled had there been in existence any English manual on water analysis which would at once indicate all the information that would be required of the analysts, while it would not carry them into minute details of analysis which it was felt are not needed for the fulfilment of the special purpose in view.

"Mr. Nicholson is most severe upon the process for the determination of alkaline chlorides; he considers it so erroneous that because of it alone he would condemn the whole scheme.

"In estimating the salts of the alkalies in a water, it is usual to convert them into chlorides; and as a part of the alkali may exist in the form of sulphate, the conversion of the sulphate into chloride may be effected by the addition of chloride of barium to the water; the barium precipitates the sulphuric acid, while the chlorine remains in union with the potassium or sodium. But if the alkaline sulphates are present in only small amount, this conversion may be more conveniently brought about by the addition of chloride of ammonium to the solution, for on evaporation and subsequent ignition the ammonium carries off the sulphuric acid, leaving the chlorine in combination as chloride of sodium or of potassium. But Mr. Nicholson utterly denies this statement, and states that any one can convince himself by a simple experiment that it is an erroneous one.

"Well, if it were a fact that the conversion of alkaline sulphate into chloride cannot thus be brought about, the error in the present case would not lead to any very serious consequences, for against such the scheme particularly guards by its direction to use chloride of barium if the alkaline sulphate is in any quantity. But the statement involved in the directions given in the scheme is in truth quite correct; sulphate of sodium is decomposed, as every chemist should know, by ignition with chloride of ammonium. If Mr. Nicholson will place in a platinum capsule a little pure sulphate of sodium, then about twice as much chloride of ammonium, dissolve in water, evaporate to dryness, and ignite till all salts of ammonia have been driven off, I can promise that he will find in the residue abundance of chloride of sodium. Of course if an obvious precaution is neglected the experiment will fail; if the two dry salts are simply stirred up together in the capsule, and if then the capsule is placed over a spirit-lamp, the chances are that—the mixture not being a sufficiently intimate one—the whole of the chloride of ammonium will volatilise before the temperature rises sufficiently high to bring about the reaction. Authorities are with the scheme on this point. Fresenius, English edition of 1865, edited by Lloyd Bullock, at pages 98 and 101, states that the sulphates of potash and soda, ignited with chloride of ammonium, are converted into their respective chlorides. The edition of 1870, edited by Vacher, repeats the statement. The very process which Mr. Nicholson condemns is taken almost *verbatim* from Fresenius, and at page 542 of the edition of 1865 it is expressly stated that chloride of ammonium is to be added, 'to convert the still remaining sulphate of soda on ignition into chloride.' I will quote one more authority. In the lately published second edition of Sutton's "Volumetric Analysis," at page 287, this direction is given:—"If the water contains but little sulphate the baric chloride may be omitted, and a little ammonium chloride added."

"Alluding to the molybdate of ammonium process, which is there recommended for the detection of phosphoric acid, Mr. Nicholson says—"It is one of the most untrustworthy known." Noad, in his "Manual of Analysis," says of this test—"It is especially useful, as it enables the operator to detect the presence of phosphoric acid in minute quantities, in acid solutions of soils, fossils, &c." Fresenius, in his direction for the qualitative analysis of water, gives this test only for the detection of phosphoric acid. Connington says the test is peculiarly fitted for the detection of small traces of phosphoric acid, as in minerals, soils, deposits from mineral springs.

Valentin orders it for the detection of the very minute traces of phosphorus in iron. I have myself used the test for many years, and have always found it reliable, and so searching that I do not hesitate to affirm that where this test fails to detect phosphoric acid in the residue, as ordered in the scheme, the presence of that body may safely be disregarded in an analysis made for the purpose of determining the fitness or otherwise of a potable water. I find, by experiment, that if the residue of say 100 c.c. of water contained 0.00002 grm. of phosphoric acid it would be readily recognised by the test, and even so little as 0.00001 grm. is recognisable if the test-tube and contents be allowed to stand some hours.

"The next point, in regard to which I have to defend the chemistry of the scheme, is in the matter of Mr. Nicholson's assertion that, in the process given for the detection of silica, the hydrochloric acid in the presence of nitrates would attack the platinum capsule, so that the residue would, in all probability, be one of platinum and silica. The scheme directs that hydrochloric acid be added to the concentrated water in slight excess, so that even at the commencement of the final evaporation there would be but a very small quantity of free acid in solution. One cannot open any work on chemical analysis without finding such a process; for instance, in Fresenius's edition of 1865, p. 542, this very process is given for the estimation of the silica in water, and the process follows immediately upon that for the estimation of nitric acid in the water.

"Mr. Nicholson complains, not of the principle of the method directed for the recognition of free carbonic acid in water, but that too large a quantity of lime water is directed to be used in applying it. It needs no such calculation as he has employed to prove, what would be patent to any one working the scheme, that a wrong figure had been retained in the text.

"Then Mr. Nicholson has a good deal of objection to make to the directions to evaporate the water down first in a porcelain capsule, and subsequently in a platinum dish. The point was fully considered, and we determined that, under the circumstances in which the operations would generally be conducted, the *alternative* plan as it stands in the scheme might very properly be recommended; and indeed, if the evaporation is not carried too far in the capsule, and if the transference is carefully conducted, the amount of silicates that will be taken from the capsule will be altogether inconsiderable. Of course if the analyst wishes to be very accurate in his estimation of silica, he will, as mentioned in the text, evaporate from first to last in a platinum capsule.

"Mr. Nicholson points out that, in the process for the quantitative estimation of silica, direction to evaporate to dryness, after the addition of the acid, has been omitted. It ought to have occurred to him, I think, that as the process is rightly given in the directions for the qualitative analysis for silica, its omission here was a mere oversight. If Mr. Nicholson will refer to the latest English edition of Fresenius, he will find that the detail dwelt on by him is there omitted in the process for the determination of silica in *potable waters*, while it is inserted in the more lengthy directions for the analysis of *mineral waters*. It has yet to be experimentally proved that the oversight alluded to would lead to serious error in the case of Indian waters.

"Regarding this, and other clerical errors which exist in the scheme, I may say I was prepared for them, for the manuscript, lined and interlined, was twice copied by mere copying clerks, so that I fully intended, on receiving a printed copy of the scheme in Calcutta, to go through the processes with the scheme before me in the laboratory, when any errors of the kind would have been at once discovered; but unfortunately, the very day I received a copy of the scheme, I also learned that Government had decided to stop water analysis in military cantonments in this presidency, intelligence which so vexed and disappointed me that I put the scheme altogether aside.

"As regards the criticisms upon the 6th Bengal Report upon the analysis of potable waters, I did not compile it; its defence may be well left to those who did.

"It is much to be regretted that systematic water analysis is for a time stayed in Bengal, for the new methods of analysis introduced by Messrs. Wanklyn and Chapman are so immeasurably superior to those formerly used, that they certainly ought to be applied to the examination of every important potable water regarding the purity of which there can be any room for doubt."

ON THE PRODUCTION OF FURFUROL BY THE ACTION OF SUPERHEATED WATER UPON WOOD.

By HUGO MÜLLER.

In confirmation of the results described by Mr. Greville Williams respecting the formation of furfural by the action of superheated water on wood, I may be permitted to mention some observations which I made some time ago whilst carrying out some experiments on the production of paper-pulp from wood.

In the course of these experiments, I had occasion to examine the action of water on various kinds of wood at a temperature varying from 120° to 180° C., and I then noticed that the resulting aqueous extract exhibited invariably a strong odour resembling very much that of furfural. Having occasion during last summer to repeat the same kind of experiments with bamboo, I observed the formation of this furfural-like odour in a still more pronounced and unmistakable degree; and I felt accordingly induced to submit the obtained aqueous extract to a special distillation in order to get some direct proof of the actual presence of furfural.

Although the quantity of bamboos in this particular experiment amounted to not more than 200 grms., I obtained, after two distillations, an appreciable quantity of a heavy oily liquid, which exhibited all the properties of furfural, and which on being brought into contact with ammonia at once gave rise to the formation of the well characterised furfuralamide.

It would appear from these experiments that superheated water shares with dilute sulphuric acid and chloride of zinc the power of splitting up the peculiar substance recognised by Gudkow some time ago as the furfural-yielding constituent of all vegetable tissues.

Although the aqueous extract containing the furfural exhibits a strong acid reaction caused by the presence of some peculiar organic acids, I do not think that the formation of furfural in this case is due to the action of these acids; on the other hand, I may mention that in treating wood with caustic soda lye instead of pure water, the formation of furfural appears not to take place.

NOTE ON LITMUS-PAPER.*

By EDWARD R. SQUIBB, M.D.

THE rapid progress of medical science, and the consequent improvement in the art of medicine, renders the modern physician much more critical and accurate in his investigation and observation of diseased conditions; and for the means by which to attain greater accuracy and precision in his observations and researches he properly and naturally looks to the pharmacist. In this way, within the past few years, litmus-paper has become an important, if not indispensable agent to the intelligent physician, and he often seeks it, but rarely finds it in the hands of the pharmacist. And when found, it is rarely of the quality or in the condition best adapted to his uses.

* Read before the American Pharmaceutical Association.

When the physician and pharmacist buy litmus-paper, they generally make the same mistake that the photographer does, and demand that it shall be deep in colour; that the blue shall be very blue, and the red very red. This is wrong in principle and in practice, particularly for physicians' uses, where slight traces of alkalinity or acidity are often important, and the palest instead of the deepest paper should always be selected. The solution made from 1 lb. of good litmus commonly requires about 200 grains of concentrated sulphuric acid to saturate it up to the point at which the colour *begins* to change to purple in its course toward redness, and this purplish tinge of pale blue, and the corresponding purplish tinge of pale red are the desirable colours, between which is the least margin of difference which is left undetected by the testing.

This large proportionate quantity of sulphuric acid indicates how comparatively roughly the carelessly made and deeply coloured litmus-papers fulfil their design; and it is the object of this note to indicate a better practice, and a better state of knowledge on this subject. To prepare good litmus-paper, the following formula may be useful:—

Take of—

Good litmus, in fine powder	1 part.
Water	4 parts.
Alcohol	1 part, all by weight.

Put these ingredients into a bottle, and shake the mixture occasionally during 24 hours; allow the sediment to settle out completely, and decant as much as possible of the clear liquid into another vessel; then put the same quantity of water and alcohol upon the sediment, shake again, and when again well settled, pour off the clear liquid for use in diluting the first portion of liquid, or for dissolving a fresh portion of litmus. Separate about one-fourth part of the first clear liquid, and add to the remainder dilute sulphuric acid until it becomes of a purple tint, or gives a purplish-blue colour to a slip of white paper; then add about one-half of the separated fourth part of the solution, and if this should entirely restore the original pure blue colour, again add diluted acid until a purplish tint is again obtained; then add the remaining eighth part of the original solution to restore the pure blue colour, or which is more delicate as a test for acidity, a very faintly purple-blue colour; then dilute this solution either with water, or with the second liquid from the litmus sediment until a slip of neutral white paper dipped into it has a pale blue or pale purplish-blue colour. Here it is necessary to remember that this paper when dry is many shades paler than when wet, and the dilution should be made accordingly. The solution for making red litmus-paper will not bear the same amount of dilution as that for the blue, and must be made of the proper purplish-red colour by the addition of dilute acid before dilution. The solutions so made will keep almost indefinitely, and may be passed on from one process to the next. The paper should be made from pure rag stock—not from bleached wood nor straw—should be quite white, and above all, must be quite neutral, and show no red spots or blotches when moistened with the blue solution. French or German filtering-paper commonly answers well if of good quality. This is cut into convenient size, the larger the better, because there is less waste, and held by two corners, which corners are to be kept dry; it is to be skillfully laid on the surface of the solution, first one side and then the other, then drained, and hung over clean glass tubes to dry. The vessel to hold the solution for dipping should be larger than the sheet of paper, and shallow.

The sheets when dry are laid together, and the edges trimmed off all round. They are then cut into sheets 3 to 4 inches wide and 12 to 18 inches long, according to the size of the paper used. What is sold as "a sheet of litmus-paper," should never be less than 4 inches by 12, or 3 by 28. Such a sheet cut lengthwise through the middle gives a strip which when cut crosswise into strips

a quarter or three-eighths of an inch wide, is of a very convenient size and form for use. The sheets, one paler and one deeper of the same colour, if desired, should be rolled up together in a tight roll, slipped into a test-tube and corked. An ordinary 5-inch test-tube holds the sheets conveniently, and one such tube of the red and one of the blue, properly labelled, forms a convenient pair, such as is supplied to the U.S. army by the writer. Formerly these sheets were enveloped in tin-foil; but though they thus keep much better than in paper, they are when pale and delicate very liable to be changed and spoiled by the alkaline and acid vapours in the air. In corked test-tubes they keep unchanged for an indefinite time, while the test-tubes and corks when empty are always worth their cost to those who use litmus paper.

In this form of sheets, however, the paper is not so convenient for the physician as when cut into strips 1 to 2 inches long and a quarter of an inch wide; and the writer finds that about 100 of such strips, put up in a wide-mouth tube vial, corked and properly labelled, is a most convenient and popular form for physicians' use. One such vial of each colour put up together forms a pair which no physician should be without. And most physicians will buy them if they can get them. These convenient little strips may be shaken out of the vial as wanted for use, but as the fingers should, by rights, never touch any other strip than the one taken, it is best to take them from the vial by a pair of forceps from the physician's pocket-case.

ON A

NEW APPLICATION OF TUBE HYDROMETERS.

By WILSON H. FILE, M.D.

In an article read before the American Pharmaceutical Association in Baltimore, 1870, I endeavoured to render intelligible a new method by which the relation between the degrees of Baumé's hydrometer and specific gravity could be easily determined; and, as the method there pointed out is intimately connected with the present subject, I will briefly recapitulate the main points.

A plain cylindrical tube of thin glass, closed at its lower end, is to be immersed in pure water, at a temperature of 60° F., and then loaded by pouring in shot or mercury until it sinks about two-thirds of its length in the water, the point to which the surface of the water rises being then marked on the tube. If now that part of the tube which was immersed in the water be divided into 145 parts, and these parts numbered from the top downwards, the tube will represent a Baumé's hydrometer for liquids heavier than water, and by floating it in any liquid of greater density than water its degree will be seen on the tube at the surface of the liquid.

These degrees can be marked on paper, and the paper inserted in the tube and pushed down to the bottom, the upper mark, or zero, being exactly opposite the mark which had been previously made on the tube.

We will now proceed to show a new application of these tube hydrometers in determining densities.

Having immersed a tube, closed at the lower end as before, in water, we pour water into the tube until it sinks about two-thirds of its length.

It should float upright. We are now to mark the surface of the water in which the tube floats, and also the surface of the water within the tube. The tube below this latter mark must then be divided into 145 parts, either by etching on the glass or—what is more practical—by drawing a scale on paper, numbering the degrees from the top (0°) downwards. In ascertaining the density of any liquid heavier than water, the tube must be emptied, and dried by rinsing with alcohol and drawing air through it by means of a long tube, then immersed in water of 60° F., and the liquid to be tried poured in until the tube sinks to the upper mark. It can then be taken out, and

the degree of density shown on the tube, if it be etched, or else by holding it on the paper scale in its proper position.

Our illustrations have been thus far for liquids heavier than water; for those lighter than water the tubes or scales require a different division. Unfortunately, Baumé's method of dividing his hydrometers rendered the degrees for those of light liquids larger than those for heavy liquids, and by comparison we find they are in the ratio of 145 to 140. In order, therefore, to make a scale for light liquids, we divide the space below the surface of the water within the tube into 140 parts, instead of 145 parts as at first; the degrees are then continued upwards 70 or more parts. These divisions are numbered at the water point 10° (another peculiarity of Baumé's scale, and running upwards as high as desired. The scale below the water point need not be marked, as it can be only used for liquids lighter than water.

The tube is used for all liquids in the same manner, namely, by pouring into it the liquid to be tried until it sinks in water down to the mark made at first on the tube; then by holding it against the paper scale marked as just described. The surface of the liquid will indicate its proper degree of density.

An advantage which the tube when used in this manner possesses, is the small quantity of liquid necessary, as the tube can be made quite small in diameter, and by increasing its length the degrees are rendered larger, and thus greater accuracy is obtained. It may also be employed in ascertaining the density of extremely heavy liquids, where no hydrometer could be found of service.

ON THE DETERMINATION OF THE TRUE ZERO OF THERMOMETERS.

By Ch. TELLIER.

It is generally admitted that the 0° of the Centigrade and Réaumur thermometers varies after a longer or shorter time, and the delicate and sensitive thermometers therefore become altered as regards the indication of the 0° when placed in melting ice or snow. According to the observations on the supersaturation of water with cold (see CHEMICAL NEWS, vol. xxvi., p. 107) thermometers are much less variable than is generally supposed, and the cause of the differences which are observed is probably due to an error made in the determination of the 0°. It may be readily conceived that unless special precautions are taken at the time of the graduation of the thermometer, the water in which it is plunged, and which is supposed to be precisely at the temperature of melting ice, may in reality be slightly above that temperature; this is the case if the walls of the vessel containing the water and ice admit more heat to the water than the melting ice can overpower: this is natural; ice does not melt instantaneously, but only in the ratio of its surface, and in proportion to the difference of the temperature of the water in which it floats, and its own temperature; and it is consequently quite possible that the water which contains the ice is not at a temperature of 0°. The colder the water the more slowly will equilibrium of temperature be established between the two bodies, and in the same ratio will the chances of error be greater. The error of indications of the thermometers brought on by time either depends upon a modification in the glass, as usually admitted, or it is due to the result of an erroneous estimation of the 0°. In the first case the alteration would rather tend to *plus* in one case and to *minus* in the other, and there is no plausible reason why it should be otherwise; in the second case (erroneous estimation of the 0°) the error should be always *plus*, because the water must be above 0°. My experiments have confirmed these views. I have taken seven thermometers

with the graduation engraved on the stem and made by one of the best makers; only one of these instruments has been found to indicate 0° correctly, all the others indicated a difference—

2	indicated	+	0.1
1	"	+	0.2
2	"	+	0.3
1	"	+	0.4

Not one of these thermometers indicated below 0°.

The determination of the 0° by placing the thermometer in melting ice is therefore not an absolutely certain method of operating. In order to find the true 0° another plan must be followed, which is that found and described by me, and called *terminus of congelation*. The operation is carried on as follows:—A glass vessel is placed in a refrigerating mixture, and the temperature of the water contained in the vessel is thereby readily lowered to -2 or to -3: this having been done, the vessel is removed from the mixture, and the thermometers to be graduated are placed in it, with a small piece of ice; hereby the water becomes suddenly frozen, while at the same time the temperature rises to 0°. When one has no ice at hand, and in order not to complicate the operation, the temperature of the water should be brought down to -4°, when, by giving a gentle tap with a glass rod to the bottom of the vessel, the phenomenon of congelation of the water will be observed, the temperature rising to the true 0° absolutely. I draw from the foregoing the two following conclusions:—

1. That the expression of melting ice does not exactly indicate the true 0°, and that therefore it ought not to be the basis of the determination of that point.

2. That by applying the term of *terminus of congelation* it is quite possible to estimate with certainty the exact point which separates liquid water from ice, and that point is the true 0°, which should be the starting point of the graduation of the thermometer scale.—*Revue Hebdomadaire de Chimie*.

CORRESPONDENCE.

TELEGRAPHIC EXPERIMENT.

To the Editor of the Chemical News.

SIR,—The following experiment may interest your readers.

On November 4th the cable from Dover to Boulogne was broken by a ship's anchor, about 5 miles from Dover. By the kind permission and co-operation of Mr. Bourdeaux, the engineer of the Submarine Telegraph Company, I placed my instrument (as shown lately before the Society of Arts, and described at the time in your Journal) between the end of the broken cable at Dover and the water-pipes of the town. To our surprise we could distinctly read every message to and from Ostend, Calais, and Dover, on the Dover-Ostend, and Dover and Calais cables. The explanation was as follows:—Part of the electrical current which went to earth at the Dover water-pipes went on to a second earth formed by the end of the broken cable, and in its passage made signals on the instrument. Thus the enormous fault formed by the Dover water-pipes was not sufficient to prevent a perceptible current of electricity passing on to the broken end of the Dover and Boulogne cable.

We also asked the French operator at Boulogne to send a current through the broken cable, and got a feeble result; but as we were not able, without special authorisation from the French Government, to get him to put on such batteries and instruments at Boulogne as were necessary, and the remaining cables were fully occupied with messages, we did not follow out this portion of the experiment. The first experiment, however, shows what an enormous fault may exist without preventing the action of

the delicate instrument, which I described in a former number of your Journal.—I am, &c.,

H. HIGHTON.

Putney, November 12th, 1872.

PREVENTING EXPLOSIONS IN COAL-MINES.

To the Editor of the Chemical News.

SIR,—By way of addition to my note "On a Means of Preventing Explosions in Coal-Mines," inserted in the *CHEMICAL NEWS* for October 25th, I beg leave to remark that in many mines the process of periodical partial exhaustion by air-pumps, followed by forcing a powerful current of air through the entire workings of the pit, would probably prove sufficient to prevent any dangerous accumulations of gas. For this purpose it would merely be necessary to have two iron plates (with suitable stop-cocks) one to cover each shaft, and to connect one or both of these with air-pumps, so as either to partially exhaust or drive in air at pleasure.—I am, &c.,

JOHN A. R. NEWLANDS, F.C.S.

9, Mincing Lane, E.C.,
November 18, 1872.

CONSTITUTION OF MATTER.

To the Editor of the Chemical News.

SIR,—Before proceeding to examine Mr. Kingzett's "objections to my arguments," I will attempt to state more fully the primitive acts and ideas on which those arguments were founded.

Matter viewed from a *physical* point of view is, in its nature, *one*. It is seen to possess the common properties of weight, extension or form, and stability, all other properties being merely conditions. It is composed of inconceivably minute particles, or atoms, which possess, like the masses of matter they compose, the common properties of weight, form or extension, and stability; but they also possess another property, of which masses of matter are destitute, viz., indivisibility. They are not alike in size or weight, but exist in great diversity of both.

Being not composed of parts, it is impossible to diminish their size by friction or "wearing" (which is a rubbing off of atoms), or by breaking (which is the act of opening matter where molecular divisions already exist); and it is impossible to increase their size by the addition of matter, because they are inflexible, and two atoms will not amalgamate together to form a larger atom (placing two atoms in contact would no more be increasing the size of one of the atoms than placing two marbles in contact would be increasing the size of either of the marbles). It is also impossible to increase their size by expansion by heat (which is the act of increasing the inter-atomic spaces of a mass of matter), because they are not composed of atoms, and have no inter-atomic spaces; and it is possible to decrease their size by cold (which is the act of decreasing the inter-atomic spaces) from the same reason.

Therefore the various atoms always retain their respective sizes, under whatever conditions the masses of matter they compose may be placed.

These variously-sized atoms, when collected into masses in their respective sizes, constitute and form a number of bodies which we call chemical elements. Each mass, owing to the different size of its component atoms, and the consequent different effect of the forces on these atoms, exhibits, when compared with the other masses, certain marked differences in its behaviour, which differences are called chemical properties. It is seen that, if all the forces could be withdrawn, "we should have matter reduced to (chemical) simplicity," because matter would then present one uniform absence of chemical properties.

But one element can never be converted into another; because, though the play of the forces develops chemical properties, yet the atomic sizes which influence the play

of the forces can never be altered by the alteration or "withdrawal of the forces."

Mr. Kingzett thinks I have "made a serious error by saying the withdrawal of the forces cannot alter the atomic sizes." "Would it not," says he, "be wiser to say the atomic size is an effect of force? For, if not, the atomic volume at 100° C. would be the same as at 0° C." Mr. Kingzett has here been guilty of "confusing matter and force." The increase in volume caused by the heat is not due to an increase in the size of the atoms, but to an augmentation of the inter-atomic spaces. Whether I have demonstrated the "most important fact," that the atoms are incapable of alteration in size, I leave it for Mr. Kingzett to consider. By mechanical means, such as crystallisation, heating from a low to a high temperature, &c., it is possible to alter the molecular arrangement, but not the chemical nature, of an element. For instance, "the diamond, graphite, and charcoal are constituted of the same matter, though the qualities of each are very different; the difference arises from molecular arrangement, or, in other words, from the ultimate particles being differently operated upon." "Yet we can burn all three forms into CO₂," which proves the identity of the chemical nature of the three forms, in spite of the fact that their "particles are differently operated upon."

To the rule that chemical nature depends on the atomic sizes, there are five known exceptions; yet a very slight difference in the form of the atom, or an exceedingly fractional error in the estimation of the atomic weight, would be sufficient to account for a difference in the chemical behaviour of two bodies whose atoms are supposed to be of the same size.

"If," asks Mr. Kingzett, "atoms are not composed of atoms, what are they composed of?" This would lead one to conclude that Mr. Kingzett advocates the antiquarian theory of the infinite divisibility of matter; he did not pay sufficient attention to the word *ultimate*, which preceded the word *atom*.

If he finds a difficulty in conceiving the idea of an atom possessed of extension and devoid of divisions, I find an equal difficulty in forming any conception of an atom containing an infinite number of divisions yet possessed of stability. Divisions are space, and where space exists matter is not. Therefore, if the divisions or spaces are infinite, there is no room for matter left; or, in other words, matter cannot exist.

"If," says Mr. Kingzett, "matter cannot exist without force, then force must exert an influence over matter under any circumstances,—therefore the size or volume of atoms is influenced by force." Mr. Kingzett places a dash between the words "circumstances" and "therefore." What mysterious train of thought is this intended to represent? I confess I am unable to see it.

Mr. Kingzett should recollect that, if "all the forces could be withdrawn, we should have matter," not annihilated, but "reduced to simplicity;" and therefore matter can exist without force.—I am, &c.,

JOHN F. SUTTON.

MISCELLANEOUS.

Indian Cinchona Alkaloid Factory.—We understand that Dr. Simpson of Patna, has declined the superintendence of the Cinchona Alkaloid Factory at Rungbee, in Sikkim, and that the Indian Government have sent home for some one to fill the appointment. We hope that an experienced chemist will be appointed.

Chemistry at Cambridge.—The Master and Fellows of Gonville and Caius College at Cambridge have recently determined to appoint a Professor in Chemistry to superintend the College Laboratory, and to have charge of the chemical studies of the students there. The stipend will be £200 a year, and the Professor will have the ordinary

status of a Fellow of the College. The election will take place about the middle of next month.

Royal Society.—The Medals in the gift of the Royal Society have this year been awarded as follows:—The Copley Medal has been awarded to Professor Friedrich Wöhler, of Göttingen, For. Memb. R.S., for his numerous contributions to the Science of Chemistry, and more especially for his researches on the products of the decomposition of Cyanogen by Ammonia; on the Derivatives of Uric Acid; on the Benzoyl Series; on Boron, Silicon, and their compounds; on Titanium, and on Meteoric Stones. A Royal Medal has been awarded to Prof. Thomas Anderson, M.D., for his investigations on the Organic Bases of Dippell's Animal Oil; on Codeine; on the Crystallised Constituents of Opium; on Piperin and on Papaverin; and for his researches in Physiological and Agricultural Chemistry. A Royal Medal has been awarded to Mr. Henry John Carter, F.R.S., for his long-continued and valuable researches in Zoology, and more especially for his inquiries into the Natural History of the Spongiadæ. The Romford medal, awarded every two years, has been awarded to Anders Jonas Ångström, For. Memb. R.S., for his Researches on Spectral Analysis. The annual meeting of the Fellows of the Society, for the election of Officers and Council for the ensuing year, will be held on the 30th inst. We understand that Prof. Huxley has been nominated by the Council as successor to Dr. Sharpey, who, after a long period of service as Secretary, resigns his office.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 11, 1872.

This number contains the following original papers and memoirs more particularly relating to chemistry:—

Composition of Chloride of Lime.—J. Kolb.—The contents of this paper relate to researches made by the author in 1867, and then published in the above-named periodical, as well as in the *Annales de Chimie et de Physique*. These researches are here referred to to correct some errors which the author considers were contained in a paper by Dr. Crace Calvert, published in the *Comptes Rendus* of 27th May last.

Causes of the Loss of Sodium in Leblanc's Soda-Making Process.—A. Scheurer-Kestner.—After first referring to his former essay on this subject (see CHEMICAL NEWS, vol. xxii., p. 267), the author states that the loss of sodium retained in the waste increases proportionately with the quantity of chalk employed. When for 100 sulphate of sodium the quantity of chalk amounts to 98, the quantity of sodium retained in the waste is 0.39 per cent; for 102 chalk to 100 sulphate of sodium, 0.86 per cent; for 111 chalk to 100 sulphate of sodium, 1.30 per cent. The greater part of the excess of chalk is converted during the calcination process into lime; and when the crude soda is lixiviated with water, the lime, while becoming hydrated, reacts upon the carbonate of sodium, and thereby renders a portion insoluble in water. According to a series of experiments made by the author, the lime may retain even as much as from 4.75 to 4.95 per cent of soda, calculated dry. The greater or less porosity (density) of the ball-soda also exerts some influence; the waste from porous ball-soda was found to contain 1.44 per cent, that from dense ball-soda 1.97 per cent of soda. In order to diminish as much as possible the loss of sodium, the quantity of chalk to be employed should be reduced as much as possible, and the thoroughly calcined mass should be withdrawn from the furnace when it gives off copiously carbonic oxide gas, which is only formed when the operation is nearly finished; the evolution of this gas being due to the action of the coal upon the limestone compound, viz., reduction of the carbonate to caustic lime.

Neutral Combinations of Mannite and its Hydrates.—G. Bouchardat.—This essay treats on dichlorhydric mannite—

a crystalline body soluble in cold water, insoluble in absolute alcohol and ether; fuses at 174° , but is then also decomposed, as is also the case when it is dissolved in boiling water, the result being the formation of monochlorhydric mannitan and HCl. The former is a neutral compound readily soluble in all proportions in water, alcohol, and in ether. When dichlorhydric mannite is treated with nitro-sulphuric acid, it is converted into hydro-chloro-nitro mannite, a solid substance insoluble in water, soluble in alcohol, not explosive; dibromhydric mannite, $\text{C}_{12}\text{H}_{22}(\text{H}_2\text{O}_2)(\text{HBr})_2$, also a solid body insoluble in cold water, alcohol, and ether; fuses at 178° with decomposition, which also ensues when this compound is treated with boiling water, thereby yielding monobromhydric mannitan, $\text{C}_{12}\text{H}_{22}(\text{H}_2\text{O}_2)(\text{HBr})$, a compound readily soluble in water, alcohol, and ether.

Researches on Santonine.—L. de Saint Martin.—Santonine is the active principle of the *Semina santonici*. The author has investigated santonine with the view of establishing its chemical character. If santonine is really a phenol its formula, $\text{C}_{20}\text{H}_{18}\text{O}_6$, indicates that it must yield by reduction:—(1) a diatomic phenol, $\text{C}_{20}\text{H}_{16}\text{O}_4$; (2) a monoatomic phenol, $\text{C}_{20}\text{H}_{14}\text{O}_2$; (3) a hydrocarbon, $\text{C}_{20}\text{H}_{18}$. The author has prepared, by treating santonine with zinc filings at a high temperature, santonol—a phenol $\text{C}_{20}\text{H}_{18}\text{O}_2$ —which in a pure state is similar to stearine, and fuses at 135° . It is insoluble in water, readily soluble in alcohol and ether, yielding with sulphuric acid a sulpho-conjugate compound.

Researches on the Functions and Transformation of Mouldiness.—A. Béchamp.—This lengthy essay contains the record of a series of experiments made with the view to prove that, chemically, mouldiness is ferment, and that there exists in that respect no real difference between the cryptogamic plants, vulgarly termed mouldiness and yeast.

Fermentation of Fruit.—G. Lechartier and F. Bellamy.—This paper treats at length on the changes which fruit, apples, pears, cherries, potatoes, and chestnuts undergo when kept for a long period in closed vessels. It appears that previous to becoming quite rotten, fruit yields under these conditions alcohol and carbonic acid; which is also evolved from grain and from linseed when sufficiently moist, and kept under the same condition for a long time.

Estimation of Manganese in Soils and in Plants.—A. Leclerc.—Reserved for full translation.

This number contains a series of papers relating to the discussion on fermentation, and a number of papers relating to astronomy, meteorology, geology, botany, physiology, and anatomy.

La Revue Scientifique de la France et de l'Etranger, November 16, 1872.

This number contains no papers relating to chemistry, but we call attention to the following memoir:—

The Troglodytes of Vézère.—P. Broca.—The illustrated account of an extinct race of mankind, of which fossil remnants are found at and near Vézère. There is added to this memoir an account of the excursion from Bordeaux to Eyzies, during the meeting of the French Association for the Advancement of Science, for the purpose of visiting the bone cavern.

Revue Universelle des Mines, de la Metallurgie, des Travaux Publics, des Sciences et des Arts Appliqués à l'Industrie, June, 1872.

In addition to several original papers strictly relating to engineering and collateral subjects, this number contains an exhaustive memoir—**Chilian Amalgamation Method.**—E. Fonseca.

Revue Hebdomadaire de Chimie Scientifique et Industrielle, November 7, 1872.

Review of the Contents of the International Exhibition Held at Paris in 1872.—C. Mène.—This first portion of a review of the exhibition of products of domestic economy treats, in the first place, on the origin and history of the exhibition, and, next, on the objects sent in from La Martinique, one of the French colonies.

Manufacture of Perfumed Soaps.—M. Beyer Brothers.—An illustrated account exhibiting the machinery and tools for the industrial preparation of perfumed soaps.

Improved Method of Obtaining Sea-Salt.—M. Rouleau.—The author describes the method of construction of the so-called salt-gardens, so as to obtain by one evaporation of sea-water (spontaneous evaporation by exposure to open air) a clean and white-coloured salt, this method of construction being especially adapted to sandy and marshy sea-shores.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 16, 1872.

Before proceeding with the ordinary business of the meeting of this society, the President, Dr. A. W. Hofmann, announced that the Runge memorial monument, the erection of which was first proposed by this society, was finished, and would shortly be placed in the cemetery at Oranienburg; the monument is beautifully executed.

This number contains the following original papers and memoirs:—

On Kieserite, its Properties and Applications.—H. Gröneberg.—Kieserite, $(\text{MgSO}_4 \cdot \text{H}_2\text{O})$, is a native product of the Stassfurt saline deposit, and is distinguished from the ordinary sulphate of magnesia, $(\text{MgSO}_4 \cdot 7\text{H}_2\text{O})$, by its being less soluble in water. The author describes at length the industrial method applied at Stassfurt for purifying this salt, so that it is sent off at 60 per cent MgSO_4 , it being

extensively used for dressing cotton and other textile fabrics at Manchester. A large quantity of kieserite is employed in winter for preparing, by double decomposition at a low temperature, sulphate of soda from common salt; the kieserite is also used as manure, and the author has succeeded in making a double salt of kieserite and gypsum, which—prepared by first mixing the two salts together, igniting this mixture, and next treating it with cold water—yields a hard marble-like mass, which, when pulverised and mixed with water, may be moulded in any shape, rapidly becoming as hard as stone, and unalterable by atmospheric agency.

The Liebenfraunsee at Kissingen.—C. Bender.—It appears that there is situated near Kissingen a small lake (size of surface, 1076 square metres), from which gas is permanently evolved in rather large bubbles; this gas was found by the author to consist, in 100 parts, of—Nitrogen, 84.6 per cent, and oxygen, 15.4; while the gas absorbed by the water was found to consist, a deduction being made for carbonic acid, of—Nitrogen, 74.7 per cent, and oxygen, 25.3. Assuming that in every second one gas-bubble of 10 c.c. is evolved per square metre of surface from this sheet of water, the quantity of nitrogen evolved in the atmosphere amounts per second to 0.2 litres. The author describes at length, and illustrates with woodcuts, the ingeniously-contrived apparatus employed by him in making these researches on the spot.

On Quercite-Sulphuric Acid, and on a Kind of Sugar Separated from it which Differs from Quercite.—C. Scheibler.—Braconnot discovered in acorns in the year 1849 a peculiar kind of sugar, termed quercite, which has the formula $C_6H_{12}O_6$, and of which Dessaignes (*Ann. d. Chem. u. Pharm.*, vol. lxxxi., p. 103) states that it yields with sulphuric acid a conjugate quercite-sulphuric acid. The author has recently prepared quercite and this acid in larger quantity, and says that the barium, calcium, zinc, cadmium, and copper salts of this acid are all amorphous resin-like materials. The aqueous solution of the barium salt, when heated to from 120° to 130° in a sealed tube, is split up into sulphate of baryta, free sulphuric acid, and a new kind of sugar, which is not quercite, and which the author believes to be identical with mannite or dulcite, and to be formed from quercite by taking up 1 molecule of water; further researches are, however, being made.

On Pheno-Chinon and Similar Compounds.—H. Wichelhaus.—After first referring to his former researches on the oxidation of phenol (see *CHEMICAL NEWS*, vol. xxv., p. 190), the author records in this memoir, elucidated by a lengthy series of complex formulæ, his researches on pyrogallo-chinon, chinhydron, pheno-chinon, and purpuro-gallin, the formulæ of which are, respectively—

1. Purpuro-gallin.— $C_{12}H_{10}O_6 = C_6H_4 \begin{smallmatrix} O.O.C_6H_5 \\ O.O.C_6H_5 \end{smallmatrix}$
2. Pheno-chinon.— $C_{12}H_{10}O_6 = C_6H_4 \begin{smallmatrix} O.O.C_6H_5.OH \\ O.O.C_6H_5.OH \end{smallmatrix}$
3. Chinhydron.— $C_{12}H_{10}O_6 = C_6H_4 \begin{smallmatrix} O.O.C_6H_5(OH)_2 \\ O.O.C_6H_5(OH)_2 \end{smallmatrix}$
4. Pyrogallo-chinon.— $C_{12}H_{10}O_6 = HO.C_6H_3(OH)_2.O.C_6H_5(OH)_2$

The author further treats on the reaction between pheno-chinon and aniline, whereby a body identical with chinon-anilid is formed.

New Phenol-Sulpho Acid.—J. Post.—After briefly referring to the researches of Kekulé, Kolbe, and Gauhe on phenol-sulpho acids obtained from nitro-phenol, the author states that he has obtained, by treating ortho-nitro-phenol, which fuses at 110°, with fuming sulphuric acid, a new phenol-sulpho acid different from those hitherto known. The lime salt of this substance is a solid crystalline body; formula—

The composition of the baryta salt is similar to that just mentioned, but the acid itself has not been isolated in pure state.

On some of the Derivatives of Uramido-Dracylic Acid.—P. Griess.—This essay treats on nitro-amido-dracrylic acid—

a solid, crystalline, deep yellow-coloured body, difficultly soluble in boiling water, but more readily so in boiling alcohol. The barium salt of this acid has in air-dry state the formula—

The author further refers to the action of tin and hydrochloric acid upon nitro-amido-dracrylic acid, on oxynitro-dracrylic acid, and on β -oxynitro-benzoic acid.

Structure of Isomorphous Crystals.—H. Baumhauer.—A crystallographical essay.

Means of Regulating Gas-Flames so as to Obtain a Constant Temperature Higher than that of the Boiling-Point of Mercury.—J. Myers.—Reserved for full translation.

New Hydrocarbon Isomeric with Anthracen.—C. Graebe.—When crude anthracen is treated with benzol or sulphide of carbon, the filtrate of these solutions contains several hydrocarbons, only one of which, viz., acenaphthen, has been isolated and studied. It appears that Dr. Glaeser, while working with crude anthracen on the large scale, has found a new hydrocarbon, which he has sent to the author for further investigation. The new compound, $C_{14}H_{10}$, is in many respects akin to anthracen; it crystallises, exhibits fluorescence, fuses at 105°, boils at 340°, is hardly soluble in cold, more readily so in hot, alcohol, and is very soluble in benzol, ether, and sulphide of carbon; vapour density, 6.28 (theoretically 6.16); it combines with picric acid, and behaves like anthracen with chromic acid.

Chlorine Derivatives of Aceton.—C. Bischoff.—This exhaustive monograph is divided into the following sections:—Introduction, con-

taining a concise *resumé* of the labours of other savants on this subject; monochlor-aceton-cyanhydrogen; monochlor-acetonic acid; salts of this acid.

Mono-Oxyanthrachinon and Anthraflavinic Acid.—C. Liebermann.—The results of the author's renewed investigation of these bodies; these results agree with those published in the *Ann. d. Chem. u. Pharm.*, vol. clx., p. 141.

Decomposition of Nitrated Anisols by Ammonia, and on the Constitution of Tri-Amido-Benzol.—H. Salkowski.—Notwithstanding its high scientific value, this essay is not suited for abstraction.

Action of Phosphoric Perchloride upon Sulphon Acids.—G. A. Barbaglia and A. Kekulé.—It appears from the researches recorded in this essay that the sulpho group of the phenol-sulphon acids is decomposed by phosphoric perchloride, with the formation of thionyl chloride—

yields—

and next—

and then—

while, at the same time, there is formed—

On some of the Substitution Products of Dimethylaniline.—G. Krell.—This essay treats on—Monochlor-dimethylaniline—

dichlor-dimethylaniline—

trichlor-dimethylaniline—

dinitro-dimethylaniline—

and trinitro-dimethylaniline—

Bayerisches Industrie und Gewerbe-Blatt, October, 1872.

This number contains no original papers relating to chemistry.

Pharmaceutische Zeitschrift für Russland, No. 15, 1872.

The original papers contained in this number strictly bear only upon pharmacy.

Nos. 16 and 17, 1872.

Testing of Fatty Oils.—H. Ludwig.—This monograph is divided into the following sections:—Colour of the oils; smell and taste of the oils; difference of fluidity and of forming drops of the oils; freezing-point of the oils; capability of drying of the oils; specific gravity—viz., oils the sp. gr. of which is between 0.900 and 0.920; between 0.920 and 0.935; above 0.935; elementary composition of some fatty oils; fatty oils and alcohol; behaviour of fatty oils with polarised light; testing the oils for admixture of resin oil; amount of heat evolved when the oils are mixed with strong sulphuric acid; colouration of fatty oils by concentrated sulphuric acid; action of *syrup-like* phosphoric acid, $\frac{1}{2}HO_3PO_3$, and oils; behaviour of the oils with nitrous-nitric acid (acidum nitroso-nitricum); fatty oils and nitric acid; peroxide of hydrogen and fatty oils; nitro-sulphuric acid and the fatty oils; chlorine and fatty oils; nitro-hydrochloric acid and fatty oils; caustic soda solution (sp. gr. 1.34) and the oils; dry hydrate of lime and the oils; Bolley's test (solution of carbonate of potassa) and the oils; Seyfried's test (acetate of lead); detection of the oil from *Crucifera* by the sulphur they contain; behaviour of some fat oils when heated; action of bichromate of potassa and dilute sulphuric acid upon oils; permanganate of potassa and fatty oils.

No. 18, 1872.

This number only contains original papers relating to pharmacy.

Les Mondes, November 14, 1872.

Project of an Atmospheric Submarine Postal Communication between France and England.—E. Martin.—In this paper the author describes a modified plan, which consists in the use of a narrow tube through which simply microscopic photographs containing the dispatches, produced upon collodion, are to be transmitted. It appears that this method of operating was first used during the late siege of Paris, and has now been improved upon. The execution of these microscopic photographs can be conducted by day or at night by the aid of the electric light. The tube through which these light pellets are to be transmitted need only be some few centimetres in diameter. The motion is imparted by compressed air.

Bibliography.—Under this heading attention is called to the following work:—"Recherches sur les Causes et les lois des Mouvements de l'Atmosphère," par J. M. Sanna-Solaro, S.J. (Paris, 1872). This volume, which is highly spoken of by its reviewer, treats on the meteorological phenomena of our atmosphere.

Obituary.—We regret to announce the death of a well-known scientific chemist, M. Poinet, who for many years has been Assistant Professor at the Conservatoire des Arts et Métiers, and at the Ecole Centrale des Arts et des Manufactures. The deceased worked during many years with the late Professor Payen, and his researches on agricultural chemistry are well and deservedly known.

American Journal of Pharmacy, November, 1872.

In addition to original papers and memoirs strictly relating to pharmaceutical sciences, this number contains the following original papers relating to chemistry:—

New Application of Tube Hydrometers.—Dr. W. H. Pile.—Reproduced in full.

Notes on Benzoïn.—A. C. Curtis.—The results of the author's researches may be summarised as follows:—That benzoïn contains, in addition to benzoic, a not inconsiderable quantity of cinnamic acid, which can be obtained in free state by boiling the resin with double its bulk of lime, in forty times its own weight of water, for fifteen minutes, filtering, cooling, acidulating strongly with hydrochloric acid, washing the precipitate, and re-crystallising from water acidulated with HCl. The benzoic acid is best obtained from the resin by sublimation, and is in that way procured free from cinnamic acid. Some benzoïn contains about one-fourth of impurities, and therefore its pharmaceutical preparations are deficient in strength unless an allowance be made for the impurities.

J. H. Johnson.—We cannot give the information. Write to Asher and Co., Bedford Street, Covent Garden.

Major W. A. Ross, Dr. E. J. Mills, and Prof. Living are thanked for their communications.

ROYAL INSTITUTION OF GREAT BRITAIN.

ALBEMARLE STREET, PICCADILLY, W.

LECTURE ARRANGEMENTS FOR 1872-73.

Subscribers of Two Guineas are admitted to all the Courses. A Single Course, One Guinea or Half-a-Guinea.

LECTURE HOUR, THREE O'CLOCK.

CHRISTMAS LECTURES (adapted to a Juvenile Auditory).

PROFESSOR ODLING, M.A., F.R.S. Six Lectures. "On Air and Gas." On December 28 (Saturday) and 31, 1872; January 2, 4, 7, and 9, 1873.

BEFORE EASTER, 1873.

PROFESSOR RUTHERFORD, M.D., F.R.S.E. Twelve Lectures. "On the Forces and Motions of the Body." On Tuesdays, January 14 to April 1.

DR. DEBUS, F.R.S. Three Lectures. "On Oxidation." On Thursdays, January 16, 23, and 30.

DR. H. E. ARMSTRONG, F.C.S. Four Lectures. "On the Artificial Formation of Organic Substances." On Thursdays, February 6 to 27.

A. VERNON HARCOURT, Esq., F.R.S. Five Lectures. "On the Chemistry of Coal and its Products." On Thursdays, March 6 to April 3.

EDWARD A. FREEMAN, Esq., D.C.L. Six Lectures. "On the Comparative Political Institutions of Different Nations." On Saturdays, January 18 to February 22.

PROFESSOR W. K. CLIFFORD, M.A. Three Lectures. "On the Philosophy of the Pure Sciences." On Saturdays, March 1, 8, and 15.

PROFESSOR MAX MÜLLER, LL.D. Three Lectures. "On Darwin's Philosophy of Language." On Saturdays, March 22 and 29, and April 5.

The Friday Evening Meetings will commence on January 17.

Friday Evening Discourses during the Season will probably be given by Wm. Spottiswoode, Esq., the Rev. Professor T. R. Birks, Edward Dannreuther, Esq., Robert Sabine, Esq., Sir H. Rawlinson, K.C.B., Professor Clerk Maxwell, James Dewar, Esq., E. J. Reed, Esq., C.B., J. Emerson Reynolds, Esq., Professor W. K. Clifford, Professor Tyndall, Lord Lindsay, Professor Odling, and others.

To the Friday Evening Meetings Members and their Friends only are admitted.

AFTER EASTER.

JOHN MORLEY, Esq. Three Lectures. "On the Limits of the Historic Method." On Tuesdays, April 22 to May 6.

J. H. PARKER, Esq., C.B. Four Lectures. "On the Evidence for the Traditional History of Rome from Existing Architectural Remains." On Tuesdays, May 13, 20, and 27, and June 3.

PROFESSOR TYNDALL, LL.D., F.R.S. Six Lectures. On Thursdays, April 24 to June 5.

PROFESSOR ODLING, M.A., F.R.S. Four Lectures. On Saturdays, April 26 to May 17.

EDWARD DANNREUTHER, Esq. Three Lectures. "On the Development of Music in connection with the Drama." On Saturdays, May 24 and 31, and June 7.

In January, the New Laboratories for research will be open for the Inspection of the Members of the Institution.

Those who wish to promote Original Discovery, either by leaving to the Institution bequests for this object, or by becoming Members of the Institution, are requested to apply to the Secretary.

New Members can be proposed at any Monthly Meeting. When proposed, they are admitted to all the Lectures, to the Friday Evening Meetings, and to the Library and Reading Rooms; and their Families are admitted to the Lectures at a reduced charge. Payment:—First year, Ten Guineas; afterwards, Five Guineas a year; or a composition of Sixty Guineas.

Prospectuses (when prepared) may be had in the hall.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES, and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

Now ready, price 6d., No. 1. of

NEW WORK BY DR. MORFIT.

A Practical Treatise on Pure Fertilisers, and the Chemical Conversion of Rock Guanos, Marlstones, Coprolites, and the Crude Phosphates of Lime and Alumina generally, into various valuable Products. By CAMPBELL MORFIT, M.D., F.C.S., formerly Professor of Applied Chemistry in the University of Maryland. Demy 8vo., cloth, with 28 Illustrative Plates or Construction Plans drawn to Scale measurements. £4 4s. [Now Ready.]

By the same Author,

A Practical Treatise on the Manufacture of SOAPS. Demy 8vo., English Type, with numerous Woodcuts and elaborate Working Drawings, pp. xii.—270, £2 12s. 6d.,

London: Trübner and Co., 8 and 60, Paternoster Row.

Lecture Notes for Chemical Students.—By EDWARD FRANKLAND, D.C.L., F.R.S., Professor of Chemistry in the Royal School of Mines, &c., &c.—Second Edition.

Complete in Two Vols. Post 8vo, cloth. Vol. 1 (Inorganic) 4s., Vol. 2 (Organic) 5s.

John Van Voorst, 1, Paternoster Row.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

THE LABORATORY will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXVI. No. 679.

NEW FACTS ELUCIDATING OUR KNOWLEDGE OF THE THEORY OF FERMENTS, PROPERLY SO-CALLED.

By Dr. L. PASTEUR.

I HAVE for a considerable time considered fermentation (properly so-called) to be a chemical phenomenon correlative with physiological actions of a peculiar nature, and I had previously proved that the ferments which excite fermentation are not dead albumenoid matters, but living organisms. I have induced the fermentation of sugar, lactic and tartaric acid, and glycerine, in fact all kinds of fermentation, in mediums exclusively mineral, thus affording incontestable evidence that the decomposition of fermentable matter is correlative with the life of the ferment, so that it is one of its essential foods. For instance, under the conditions just alluded to it is impossible that there should be, in the constitution of the ferments which are generated, a single atom of carbon which is not derived from matter suitable for fermentation. The chemical phenomena of fermentation are distinguished from many others, and more particularly from those of the acts of life in its ordinary sense, by the fact of the decomposition of a far greater weight of fermentable matter than that of the ferment in action. I have long thought that this particular character is related to that of nutrition without contact of free oxygen. Ferments might therefore be considered as living beings, but endowed with a life, *sui generis*, in the sense that they possess the property of accomplishing all acts of life, procreation inclusive, without in any way requiring atmospheric oxygen. The mind here recurs to those singular infusoria which induce butyric or tartaric fermentations, or certain putrefactions, and which not only live and multiply without oxygen, but are even killed and cease to induce fermentation as soon as oxygen gas is dissolved in the liquid, or soft semi-solid substance, in which they live. By direct experiments made with beer-yeast I have found that, if the life of that very small cellular plant were partly dependent upon oxygen, it would, according to the proportion of intensity of that influence, partly lose its character of ferment; that is to say, the weight of yeast formed under these conditions during the decomposition of the sugar would gradually become greater, and approximate to the weight of decomposed sugar when gradually the life of the yeast plants continues to linger on in the presence of increasing quantities of free oxygen. Guided by these facts, I have been led to consider fermentation as a *conditio sine qua non* of the manifestation of life, when that life exists beyond the direct combustion due to free oxygen gas. As a consequence of this theory, we may consider that every being, every organ, every cell, which lives, or can continue to live, for any length of time, either without any atmospheric oxygen at all, or only in a very limited proportion, for its whole existence, is to be regarded as possessing the character of a ferment in reference to the substance which supplies it either wholly or in conjunction with heat. This substance must of necessity be oxygenated or carbonated, since, as already stated, it yields food to the ferment; because all *fermentescible* substances contain these two elementary substances. Let us take, for instance, a saccharine liquid, suitable for the food of ferments, and place it in a vessel in such a manner that we can put into that liquid any special organised production, so that no other organisms can afterwards, unknown to the experimenter, betake themselves spontaneously—that is to say, germs

suspended and floating about in the air—into the same liquid. Upon that liquid let us place a trace of pure *mycoderma vini*, and we shall find that after a few days the surface of the liquid is covered with mycoderma, in the shape of a thin, but continuous film, and that the development of the mycoderma under these conditions gives rise to absorption of atmospheric oxygen, which is replaced by carbonic acid, while, on the other hand, no alcohol is formed.* Let us repeat this experiment, under precisely the same conditions, and, when the film of mycoderma is fully formed, let the vessel be so shaken about that the film is as much as possible submerged, because the fatty matter adhering to it prevents its becoming readily moistened and totally submerged; and we shall find that on the next day, or even in a few hours, if the vessel and contents are kept at from 25° to 30°, small gas bubbles are evolved from the bottom of the vessel, proving that the alcoholic fermentation has set in. This continues for some days, although weakly, and it is easy to obtain from the liquid perceptible quantities of alcohol. Microscopic examination of the submerged cells of the mycoderma proves that they are not reproduced, but that they become swollen and the interior structure of their plasma greatly altered. If the fermentation ceases, it can be again set in action by causing the freshly-formed film of mycoderma to be submerged afresh in the saccharine liquid.

The interpretation of these facts is not difficult, because we see in these comparative experiments cells which, at the desire of the operator, become ferments or cease to be so. The question arises, What is the difference in the condition of existence of the cells of the *mycoderma vini* in each of these cases? In the first, the life of the plant on the surface of the liquid continues and is kept up by the atmospheric oxygen; while, in the other case, that life continues and is sustained beyond, and without the influence of oxygen, or at least under the influence of a very small quantity only of that gas, because that which may have become dissolved in the fluid is retained by the living cells left on the surface of the liquid. That life is not extinct in the submerged cells is proved by microscopic research, as well as by the fact that the cells induce fermentation. I will not speak here of a case in which the sporules placed upon the surface of the liquid produce real beer-yeast, because I shall have another opportunity of returning to that subject. We see, in this double experiment, on the one hand, the life or multiplication of cells, with absorption and assimilation of free oxygen, and formation of a corresponding volume of carbonic acid; and, on the other, the continuation of the life of a portion of these cells when submerged, and without the aid of oxygen gas, but with the correlative appearance of alcoholic fermentation, that is to say, a continued evolution of carbonic acid gas and production of alcohol.

It is rather curious that similar experiments made by me succeed with ordinary mouldiness; the *Penicillium glaucum*, for instance, which lives in contact with free oxygen, and takes up as much of it as it can consume for the purpose of accomplishing all the acts of its nutrition and rapid development, does not produce alcohol at all, but as soon as this cryptogamic plant is deprived of oxygen, and submerged under a liquid fit for the production of the phenomena of fermentation, its character changes entirely, and this change is accompanied by the production of alcohol and carbonic acid precisely in proportion to the duration of the acts of nutrition of the plant under its new condition of existence.

Beer-yeast, that type of ferments, and the other organised ferments which I have discovered, may therefore be con-

* I have previously said that the mycoderma has two modes of living (existence)—that is to say, that it is either mouldiness or ferment, according to circumstances—and that the beer-yeast of so-called bottom fermentation is no other body than mycoderma, which is converted into that yeast when deprived of the contact of atmospheric oxygen. I ought also to observe that the phenomena which characterise this conversion are rather complicated, but that I shall soon be enabled to give all the particulars of it. I am bound to make this observation here because I speak above of *mycoderma vini* in terms somewhat different from those here used.

sidered as plants or animals which differ from lower living organisms in that the former are endowed with the faculty of living and multiplying, beyond the contact of air, regularly and for a prolonged period of time. I have reason to believe that the mystery of fermentation is explained and elucidated by the results just alluded to.

By organised ferments we mean such organisms as are capable of continuing their existence, and of multiplying without the necessity of free oxygen for the purpose of burning and setting in action the materials of their nutrition; organisms, in other words, which can directly assimilate oxygenated matters capable of supplying heat by their decomposition, such, for instance, as sugar. Viewed in this light, fermentation appears to us as a peculiar case of a very general phenomenon; and we might say that all living beings are ferments in certain conditions of their lives, because there do not exist any in which momentarily the action of free oxygen could not be suspended. Let any living being be killed by asphyxia, by section of nerves, &c., or let any organ in such a being be deprived of life, the consequence is that since physical and chemical life cannot be instantaneously extinguished it will continue, and if that happens with privation of free oxygen (interior or exterior), then the being, the organ, the cells, will forcibly take the heat they require for their new acts of nutrition or for change in their tissues from the materials by which they are surrounded. From that moment they will decompose those materials, and we shall see the proper character of fermentation appear if the quantity of heat developed corresponds to the decomposition of a weight of fermentable matter perceptibly larger than the weight of materials set in action by the living being, by the organ, or by the cell.

The following facts appear to me to be the logical deduction of these principles. Dr. Bérard has told us (in a published memoir) that when fruit is placed in air or in oxygen gas in an enclosed space, a certain volume of that gas disappears, and an almost equally large bulk of carbonic acid gas is substituted for it. When the fruit is placed in a similar manner in carbonic acid or any other inert gas, a very perceptible quantity of carbonic acid gas is still formed, as if, says Dr. Bérard, it were developed by a kind of fermentation.

The following is, to my view, the interpretation of these facts. When fruit or any organ whatsoever is separated from the plant or from the animal of which it formed a part, life is not at once extinct in the cells which are component portions of such fruit or part of animal. The ripening of fruit after having been gathered is a palpable proof; if air is present, oxygen intervenes and plays a part in the changes which take place in the interior of the fruit. The heat is derived from the combustion which is the result, and in which the sugar plays a great part; but in that case there is no difference between the nutrition then taking place and that which occurs when the fruit is still upon the tree, and is characterised by living beings by this, that the weight of the materials transformed or set in activity is comparable to that of the materials which serve the purpose of food. It is clear that under such conditions no alcohol nor carbonic acid can be formed, except accidentally, any more than when the *mycoderma vini* lives with a supply of free oxygen.

In these conditions for every volume of carbonic acid produced a nearly equal volume of oxygen is consumed; it is in fact, ordinary respiratory combustion. Let the fruit be placed in an atmosphere of carbonic acid, and it will be found that life continues by taking from the decomposition of the sugar the heat it requires for its sustenance. The cells are then in the condition of those of ferment which live beyond free oxygen, as is the case with the cells of *mycoderma vini* when submerged. Almost as soon as fruit is placed in carbonic acid, alcohol is formed along with that gas, and although the quantity of it be small it is quite apparent; for in my experiments, 24 plums gathered from the tree and placed in carbonic acid gas yielded after a few days 6.5 grms of absolute

alcohol, while the fruit had not undergone any change, but was quite sound. A corresponding quantity of sugar had, of course, disappeared. 24 plums of the same sort, left in contact with air, had become soft watery, and very sweet. Grapes, melons, and all fruits containing acids behave in the same way. A rhubarb leaf placed in an atmosphere of carbonic acid gas gives off, after 48 hours, a somewhat vinous smell, while the leaf apparently is not at all altered, and it yields, on distillation, small quantities of alcohol. I am certain that when the operations are carefully conducted, no beer yeast nor any other ferment is formed. It is only in rare and exceptional cases that ferment cells can penetrate into the interior of fruit. Grapes deserve particular attention in this respect. Everyone may have observed that during the time of wine-making the juice of the freshly pressed grapes, and even the fruit itself, when taken from the tubs, taste and smell quite differently from grapes eaten from the stalks. It is thus with grapes kept in carbonic acid gas for some time. On being taken out of that gas, they have precisely the same taste and smell as fruit in the press-tub. This is due to the fact that during the wine-making the grapes are suddenly plunged into an atmosphere of carbonic acid.

I have no doubt the study of the phenomena here alluded to, when applied practically to the gathering of grapes, might become useful for the art of wine-making, and I should not be surprised if, by preserving bunches of ripe grapes in an atmosphere of carbonic acid, it were possible to prepare specialities of wine and brandy which would be highly valued in commerce.

I have not had time to study these points of view in animal organs. It is probable that the phenomena may differ from those exhibited by vegetable cells. Very likely the equations of all these fermentations of a new species will differ not only with every kind of cell, be it animal or vegetable, but in each instance, according to their proper nature. The few experiments made by me upon organs of the animal kingdom are too incomplete to be spoken of here, but I believe that—reasoning from the results obtained—a new view will be for physiology and pathology, and I hope that much light will be thrown on the phenomena of putrefaction and gangrene, while the production of putrid gases beyond the reach of organised ferments will receive an equally sound explanation as the formation of alcohol and carbonic acid beyond the presence of cells of alcoholic ferment.—*Comptes Rendus*.

ON OXY-AMMONIAS AND PHOSPHINE BASES.

By SAMUEL E. PHILLIPS.

THE recent and valuable researches of Hofmann on the oxidation of phosphine bases necessitate a re-examination of the many disjointed facts which confuse the literature of chemical science. The isolated aspect of Hofmann is one of numerical ingenuity, but that the radicals of nitric acid or phosphinic acid consist of NO_2 , or PO_2 , are points of the very slenderest hypothesis.

In writing a paper on the amides some 20 years ago, we contended that they were intermediate between the basic ammoniums on one side and acid ammoniums on the other, and that the latter rose in the electro-series, and were more definitely acid in proportion as the radical replacements of H were more negative or acidifying.

It was then contended that "acid + ammonia = 2HO = the amide;" while "2 of acid + ammonia = 4HO = the aminic acid." Since then a fertile extension of this generic law has opened up in the kindred formula, "alcohol + ammonia = 2HO = a basic amine," of which the sugar-salt of M. Bouchardat is a recent illustration; "glucose + ammonia = 2HO = glucosamine" (like the glucosaniline of M. Schiff). The platinum salt is—
($\text{C}_{12}\text{H}_{11}\text{O}_{10}$) $\text{H}_3\text{NCl} + \text{PtCl}_2$

The obstinacy of Berzelius in admitting that Cl might replace and function to some extent the positive or basic H has been felt in my own case, in regard to the more exceptional replacement of H by O. Meanwhile, the facts typified in hydroxylamine have slowly accumulated until the crowning and brilliant researches of Hofmann have prompted this review.

Before proceeding to minutiae, it may be well to offer an open breast and pay still further homage to the new school of thought in the admission that hydroxyl (HO_2) may, peradventure, in some weak and inconspicuous instances, function as a radical and replace one H.

The botanist wisely discriminates between normal types and monsters, and it would be well if a like logical care were evinced in chemical philosophy.

The fixation of 2 or more atoms of O in organic radicals is typical of the negative hydrocarbons, and is far more exceptional in those which have a larger proportion of H.

The hydrocarbon of acetic acid is normally ($\text{C}_4\text{H}_5\text{O}_2$), and is exceptionally (C_4H_3); just as that of alcohol is normally (C_4H_5), and exceptionally ($\text{C}_4\text{H}_3\text{O}_2$).

Admitting that ($\text{C}_4\text{H}_5\text{O}_2$) or (EO_2) and ($\text{C}_2\text{H}_3\text{O}_2$) or (MeO_2) may function as radicals, and replace one H, it may be possible that in a more exceptional case (HO_2) may do so likewise. This cautious admission, however, should in no way justify the curious and frequent use made of hydroxyl, and much less of potassoxyl (KO_2). We stay not here to consider the paucity of evidence, or the intense unlikelihood of such dispositions of atomic force, nor can we enter upon the tempting subject of polyamines or condensed ammonias. The outset or first stage of that action is, however, of so common a character, and enters so largely into ordinary chemistry, that we cannot pass it over without a few remarks.

Ammonia ordinarily exists in two forms, each of which has its hydride or non-combining characteristic, and each has its combining function as a base or an acid. The hydride forms are typically $\text{H}_3\text{N}=17$ and H_3N , or (H_6N_2)=34, both ordinarily 2 vols. One is ammonia, and the other may be called atmonia. I say typically, because atmonia in its simplest form is as yet hypothetical, though its forms abound in every manual of the science.

A confused assemblage of modern types subsist by which atmonium forms consist of 8H elements, or their equivalents, and the erroneous assumption is, that the hydride combines with two atoms of acid, as contradistinguished from a simple ammonia which combines with one only.

The simple truth is the opposite of all this; for whereas ammonium = 4H to one N, so atmonium typically consists of 7H to two N; and as both affect the same volume, so both unite similarly with one atom of acid to form compounds of similar types, and similar general properties. This confusion is well exemplified in a paper on the platinum compounds by Professor Odling (CHEMICAL NEWS, vol. xxi., p. 289). Comparing ethylamine with ethylenamine, he tabulates the distinction thus:—

Monamine Type.	Diamine Type.
KCl (4)N, Cl	BaCl ₂ 8N ₂ ''Cl ₂
KHΘ .. (4)N, HΘ	Ba(HΘ) ₂ .. 8N ₂ ''(HΘ) ₂

The true chloride of ethylenamine would be (7) N_2Cl , strictly comparable with the ethylamine chloride. The above bichloride (?) the so-called "hydrochlorate," is the chlorhydrate of ethylenamine, (7) $\text{N}_2\text{Cl} + \text{HCl}$; like the—

Hydrate of ammonium, (4) $\text{NO} + \text{HO}$
Hydrate of ethylenamine, (7) $\text{N}_2\text{O} + \text{HO}$,
The crystallised hydrate, (7) $\text{N}_2\text{O} + 3\text{HO}$

Whether the barium chloride is better notated as BaCl_2 , and the hydrate $\text{Ba}(\text{HO})_2$, or as I should prefer it, BaCl and $\text{BaO} + \text{HO}$, involves a wide question of diatomic philosophy which I am anxious to avoid in this connection; hence my numerical or typical representations.

The Professor says, "The double ammonia (ethylenamine) combines with 2 atoms of hydrochloric acid to

form the definite hydrochlorate." Precisely; but the same necessity equally exists with the simple ammonia! In either case 1 atom of acid forms the chloride, and 2 atoms yield the chlorhydrate, and similarly with the oxide and hydrate.

Nobody contends that the condensed or di-acids combine with 2 atoms of base, or that the di-alcohol, or diglucoses replace 2 of H; and yet they are directly comparable with the double ammonias or diamines.

For every chloroplatinate of ammonium, (4) $\text{NCl} + \text{PtCl}_2$, we have a corresponding platinate of atmonium—

Urea is a di-carbamide, yet we know that the acetate is normally (7) $\text{N}_2\text{O} + \text{AcO}$, or $(\text{CO})_2\text{H}_2\text{N}_2\text{O} + (\text{C}_4\text{H}_3\text{O}_2)\text{O}$.

Similarly M. Gentz gives us di-xylyl guanidine, $(\text{C}_{16}\text{H}_9)\text{CyH}_3\text{N}_2$, and the platinate salt—

M. Cahours and Gal give chlorides of both ammonium and atmonium.

Chloride of gold arsine	$\text{E}_3\text{AuAs}_2\text{Cl}$
" " palladium arsine	$\text{E}_3\text{PaAs}_2\text{Cl}$
" " platinum "	$\text{E}_6\text{PtAs}_2\text{Cl}$
	Me_3PtAsCl

Hoping that these preliminary remarks may have cleared the way, we proceed to a brief glance at the oxy-ammonias; and first among these stand the hydroxylamines of M. Lossen.

Hydroxylamine	$\text{H}_2(\text{HO}_2)\text{N}$
Di-ethylamine	$\text{E}_2(\text{HO}_2)\text{N}$
Di-benzylamine	$(\text{C}_6\text{H}_5\text{O}_2)_2(\text{HO}_2)\text{N}$
Tri-benzylamine	$(\text{C}_6\text{H}_5\text{O}_2)(\text{C}_{14}\text{H}_3\text{O}_4)\text{N}$
Hydroxamylene ammonia ..	$\text{H}_3(\text{C}_{10}\text{H}_{17}\text{O}_2)\text{NCl}$
By abstraction of 2HO	$\text{H}_3(\text{C}_{10}\text{H}_9)\text{NCl}$
Hydroxethylen tri-ethylamine	$\text{E}_3(\text{C}_4\text{H}_5\text{O}_2)\text{NCl}$
Chloroplatinate "	" " $\text{NCl} + \text{PtCl}_2$
Chloroaurate	" " $\text{NCl} + \text{AuCl}_3$
Hydrate	" " $\text{NO} + \text{HO}$
Homologue of choline	" " $\text{NO} + \text{HO}$
Hydroxylamine urea	$(\text{CO})_2\text{H}_2(\text{HO}_2)\text{N}_2$
Chlorhydrate "	$(\text{CO})_2\text{H}_4(\text{HO}_2)\text{N}_2\text{Cl}$
Semi-chlorhydrate of hydro-	$\text{H}_3(\text{HO}_2)_2\text{N}_2\text{Cl}$
xylamine	
Sesqui-chlorhydrate of hy-	$\text{H}_7(\text{HO}_2)_3\text{N}_3\text{Cl} + \text{HCl}$
droxylamine	

These are culled from various memoirs given during the last few years; and the names, types, and ideas involved, are certainly grotesque. But it is not a little remarkable that they all, without one exception, conform to the principles of an older and simple chemistry, which is now seen adequate to comprehend the most exceptional cases of modern research.

As to the homologue of choline, the type is perfectly identical with the glycol-ethylamine produced by M. Wurtz, who found it to be identical with the choline of liver, or the neurine of brain.

Next come the antimony and arsenic bases, and their oxyaminic acids, of which I have by me just now only the slender enumeration of Lowig.

The methyl-arsine, Me_3As , would seem strictly analogous by Hofmann's Me_3P . Of the ammoniacal forms Me_4As , and their oxides and chlorides, and corresponding salts, we say nothing here as they are so simple and well known. The Me_3As affects 2 vols. like the corresponding Me_3N , or H_3N , &c.

Lowig gives methyl, ethyl, and amyl forms of these bases, and lays stress on the peculiarity (?) that whereas the tetra forms (ammonium) combine with 1 O.Cl.S, &c., the tri forms (ammonia) combine with 2 atoms. Of course they do, to the production of the combining ammonium type; and methinks a fuller development would exhibit hydroxylamine varieties. Speaking of the oxide he says, "It behaves like an inorganic base,

and with acids gives soluble crystallisable salts," $\text{Me}_2\text{OAsO} + 2\text{HO}$, &c.

The antimony bases are doubtless strictly parallel, but a confusion subsists with kakodylic acid, and probably hydroxymaline varieties. That (H_2N) is a radical, replacing 1 H, is generally admitted; but whether it combines with elements atom for atom is not so clear. The corresponding E_2P , or Me_2As , do so combine, and give us oxides, chlorides, or sulphides! The oxide of kakodyl, Me_2As , "is a real base, and combines with acids to form crystallisable salts." Kakodylic acid is best regarded as an oxaminic acid, and, like the corresponding phosphinic acid, "it resists the action of the most powerful reagents."

The sulpho form is equally definite with sulpho bases, and there is a corresponding chloro type—

Lastly come the phosphine series of Professor Hofmann. Chemists will very highly appreciate his refined and beautiful improvements in the production of phosphine bases, but these products are too simple and well-known to occupy us in this connection. At the outset of this comparison, however, a great difficulty subsists in the italicised statement that the oxidised tri-methyl phosphine "is no longer capable of forming saline compounds;" whereas we have seen that the corresponding arsine "behaves like an organic base." Whether viewed as a simple oxy-ammonium, or as a possible hydroxylamine variety, in either case we think it ought to dedouble in weakly saltic forms, and thus destroy the numerical symmetry of the Hofmann series.

The great step involved in the easy production of the mono- and di-phosphines is stated with much force and interest. The formula of production, so well put, is, however, further simplified by omitting unnecessary diatomic doubling.

Primary Phosphines.

(E = Ethyl or other radical.)

Secondary Phosphines.

Tertiary Phosphines.

Quaternary Phosphines.

The first of these is described with much interest, and the chloride, iodide, sulphide, sulphate, and chloroplatinate are spoken of—

The second evinces a still greater tendency to oxidation than the first; however, it easily unites with acids to the production of crystallisable salts, just as we have seen with Lowig's arsine analogues. The chloroplatinate is $\text{E}_2\text{H}_2\text{PCI} + \text{PtCl}_2$. But the main interest attaches to the oxidation of these bases; I give a comparative list:—

Hofmann.		Phillips.
H_3P fixes 4 Θ and = HO		$\text{O}_4\text{P}_1\text{O} + 3\text{HO}$
	HO } PO	(Phosphoric acid.)
	HO } PO	
EH_2P " 3 Θ " = CH_3		$\text{MeO}_3\text{PO} + 2\text{HO}$
	HO } PO	(Methyl-phosphinic acid.)
	HO } PO	
E_2HP " 2 Θ " = CH_3		$\text{Me}_2\text{O}_2\text{PO} + \text{HO}$
	HO } PO	(Dimethyl-phosphinic acid.)
	HO } PO	
E_3P " 1 Θ " = CH_3		$\text{Me}_3\text{OPO} + \text{HO}_3$
	CH_3 } PO	(Tri-methyl-phosphinic oxide.)
	CH_3 } PO	
To this I add E_4P fixes 4 Θ		$\text{Me}_4\text{PO} + \text{HO}.$

The stability of the first is striking when compared with the isomeric and weakly "methyl-phosphorous acid (phosphide of methyl), $\text{MeO}, 2\text{HO} + \text{PO}_3$; but how may we analyse its typical character with data so vague as the following. The lead salt is given " $(\text{CH}_3)_2\text{PtPO}_3$, or perhaps more correctly $(\text{CH}_3)_2\text{PtP}_2\text{O}_6$. Analysis showed the barium salt to be $\text{C}_2\text{H}_6\text{BaP}_2\text{O}_6 = (\text{CH}_3)_2\text{H}_2\text{BaP}_2\text{O}_6$!" I believe these two salts to be—

The second is evidently monobasic; it is well and clearly defined, and corresponds with the analogues described by Lowig:—

The third body we have referred to as anomalous, and we unhesitatingly predict for it a weak saltic dedoublement; and if so, the hydrate would complete my series.

Hofmann speaks of the typical representative of his series as "tribasic ortho-phosphoric acid"; whence it follows, if the notation has any meaning at all, that the ordinary acid is PO , with 3 atoms of hydroxyl base, that the fourth is the same with 3 atoms of methyl base, and intermediately with the others; but how ill this accords with the facts is well seen by my representation of the facts.

The typical acid is a pure oxy-acid, and combines with 3HO, 3KO, or 3MeO, &c.

The first derivative is a "methyl-phosphoric acid," which combines with 2 atoms of HO, KO, MeO, &c. The third would be a tri-methyl acid were it not too basylous; replace the 3 atoms of Me by a more negative hydrocarbon, and it would be weakly acid, or with 1 H it is distinctly basic, while with 1 O it is equivocally intermediate.

In so far as my types represent these facts they are independent of any theory, and absolutely true.

As modern chemists will persist in the prolific multiplication of hybrid details with an impetuosity which disdains the higher study of the unity and simplicity of law, I feel bound to give a reluctant glance at a few of the modern memoirs in connection herewith.

M. Michaelis (CHEMICAL NEWS, vol. xxv., p. 57), gives some varied phosphine chlorides:—

As S is a very unusual constituent of ammonia, I give a few from M. Merz and W. Weith (CHEMICAL NEWS, vol. xxiii., p. 299).

Aniline		$(\text{C}_{12}\text{H}_5)\text{HHN}$
Thio-aniline		$(125)\text{SHN}$
The chloro-platinate		$(125)\text{SH}_2\text{NCl} + \text{PtCl}_2$
The sulphate		$(125)\text{SH}_2\text{NO} + \text{SO}_3$
The oxalate		$(125)\text{SH}_2\text{NO} = \text{C}_2\text{O}_3, \text{ \&c.}$

Schutzenberger (CHEMICAL NEWS, vol. xxvi., p. 26) gives some alcoholic platinum chlorides—

And similar series with $(\text{C}_2\text{H}_3\text{O}_2)$.

Also "phospho-platinous chloride		$\text{Cl}_3\text{PtCl} + \text{PtCl}$
" platinic		$\text{Cl}_6\text{PtP}_2\text{Cl} + \text{PtCl}$
" platinous acid		$(\text{HO})_2\text{PtP}_2\text{Cl} + \text{PtCl}$
" platinic "		$(\text{HO})_6\text{PtP}_2\text{Cl} + \text{PtCl}$

M. Chevrier in the *Journal of the Chemical Society* gives some further variations:—

M. Saillard (CHEMICAL NEWS, vol. xxvi., p. 23)—

It is curious to observe that the index plainly points to a future resolution into one large group of "ammonia combinations" of all the nitric and phosphoric acids, and their analogues.

Between these ammonia acids on one side, and the ammonia bases on the other, I see no line of separation or distinction whatever; and if we represent by X, oxygen or other negative constituent, and by M, hydrogen or the more basic metals, then it will be found that the same laws of type and constitution equally subsist throughout the — or + regions.

Just as X_2N is inic or combining, and X_3N non-combining, while X_4N is eminently inic, so the same laws subsist with (M_2N) , M_3N , and (M_4N) .

On the one side we have NO_2 and NO_4 , the radicals of nitrous and nitric acid, and on the other the perfectly analogous substitutions with (H_2N) and (H_4N) , while $(NH_2)H$ is hydridic or non-combining.

Just as the nitrous combinations are weak and slender as compared with the nitric, so the basic forms of (H_2N) , are still more slender and inconspicuous.

As no amount of hydrid or unstable variety seems to satisfy the cravings of modern chemistry for new and abnormal forms of combination, so this view may be acceptable as indicating a new field in condensed nitric, phosphoric, and other acids.

We have nitric acid $O_7NO + HO$; why not di-nitric $O_7N_2O + HO$, or tri-nitric $O_{10}N_3O + HO$ analogous to the corresponding di-amine and tri-amine bases?

Since writing the above, and looking round for phospho varieties, we observe in addition to the chloro-sulphide ammonias of M. Chevrier, with their alcoholic derivatives, the phospho-amides of M. Schiff and Dr. Gladstone.

The resolution of the former is plain and easy beyond measure; the latter are under investigation, and are full of interest and promise. They involve a new feature of amide (H_2N) , ammoniacal substitution, and undoubtedly contain the very condensed phosphoric acids anticipated in the above paper.

ELECTRICITY OF PLANTS.

In the *Sitzungsberichte* of the Bavarian Academy, Dr. Ranke has recently described some researches on this subject.

Our knowledge of animal electricity is in great part due to Du Bois Reymond, who showed that, while the life of tissues continues, electric currents pass through the organs according to definite laws, and in correspondence with the various phenomena of life. It was reasonable to expect that in plant organisms something analogous would be found to occur. The vital phenomena in the two cases are not qualitatively different; but, in the case of animal life, exchange of material stands out more prominently, and in the case of plant life, assimilation.

The electric current observed by Du Bois Reymond between a wound and the uninjured coating of a muscle is not to be understood as a true animal electricity. It arises from the heterogeneous nature of the wound-surface acting with greater electromotive force on the electrode applied to it.

Buff and Heidenhain observed a current on similar treatment of plants, and they rightly attribute it to the chemical and electromotive difference between the sap flowing in the wound and the water with which the uninjured surface is moistened for the other electrode. It has no connection with the process of vegetation.

Dr. Ranke, experimenting in this way, observed the wound-surface to be negative with regard to the uninjured surface, and he names the currents thus produced false currents.

Between uninjured parts of the longitudinal surface, or between parts not become very heterogeneous (through soiling with sap or otherwise) Buff observed no regular current, and Dr. Ranke's experiments confirm this. They do not, however, confirm Buff's other observation, that no regular electromotive action was to be observed between the internal parts of plants.

As to this latter point, it was necessary, in the mode of observation, to guard against the development of false currents from heterogeneities of surface: to see that the two electrodes were not unequally soiled by the escaping sap. For example, more of the fluid flows from a cross section than from a longitudinal section; hence, an electrode being applied to each, the action on one would be greater than that on the other. Another source of possible error lay in chemical heterogeneity, as, e.g., if one electrode were applied to a part of the tissue having an alkaline reaction, the other to a part having an acid reaction, in which case currents (similar to the false) would be obtained. To guard against this, only those plants were taken in which no trace of a difference of reaction was observable. The petioles of *Rheum undulatum* proved serviceable in this respect.

Another point of importance was the fibrous structure. As in the electricity of animals, the electromotive action was observed where the fibres did not lie parallel to the longitudinal axis.

The pieces experimented with, then, were cylindrical pieces from the petioles of the *Rheum undulatum*, their longitudinal axis corresponding with the axis of the petiole; and they were terminated by two cross sections perpendicular to this axis. They were 2 to 3 c.m. length, and 0.5 to 1.5 c.m. diameter of section. The apparatus for measuring the currents was similar to that used by Du Bois Reymond in his experiments.

If a piece of the kind described was taken, and one electrode applied to the cross section, the other to any point of the uncut epidermis, the false current appeared, the cross section being negative to the other surface. If now the outer surface of the piece was removed by cutting parallel to the axis, and the electrodes were applied, one to the cross section, the other to the surface laid bare as described, there was in every case a current observed, the direction of which was from the surface of cross section to the other (through the wire); hence the reverse of the false current, and of the currents in muscles and nerves. This is the true plant current, the expression of the real electricity of plants; Dr. Ranke styles it the strong current, using in this and in other cases a terminology corresponding to that of Du Bois Reymond. By a further cutting of the piece, either perpendicular or parallel to the axis, the current at first sometimes increases, but it gradually becomes weaker as the process is continued.

Du Bois Reymond named an imaginary cross section in the centre of a cylindrical piece of animal tissue the equator, and a line through the middle of the cross section the axis. When he applied the electrodes to two points of the cross section, which were symmetrical to the axis, or to two points of the longitudinal section, which were symmetrical to the equator, there was no current. But if the points were not thus symmetrical, there was a current; in the one case, the point more distant from the axis being positive to the nearer; in the other, the point nearer to the equator being positive to the more distant. In plants, something quite analogous is observed, the dissection of the currents, however (named like those of

Du Bois Reymond, the weak currents), being reversed. Thus, in the case of plants, where two unsymmetrical points are taken in the cross section, that which is further from the axis is negative to that which is nearer. And of two unsymmetrical points on the longitudinal section, that which is nearer to the equator is negative to that which is more distant.

Further, in pieces cut of a rhombic form, currents were observed analogous to those Du Bois Reymond observed in similarly cut muscles, from the acute to the obtuse angles; but in the plants the direction was reversed.

* Another point of correspondence between animal and plant electricity is that the currents only appear during the life of the tissue. The reaction of tissues which show animal electricity is always more or less alkaline, or neutral. After separation of the tissue from the living body, an acid reaction is gradually produced, and when this has taken place the electromotive action disappears. The living tissue of plants, on the other hand, is generally more or less acid, and in the death of the tissue an alkaline reaction is produced, and then, also, the electromotive action is extinguished.

Dr. Ranke experimented with a large number of plants besides *Rheum*, and found in each case the same laws of electromotive action to hold good where the fibres were arranged parallel.

Experiments were also made with pieces in which the fibres were not parallel, as in the case of certain roots; and the normal electric currents were met with if the shape of the root did not depart very much from the cylindrical, was not very conical. If, for the point of application of an electrode on the longitudinal section, a part of the root was chosen at which the tissue branched off, this acted as a cross section, and the current might be reversed. The same remark applies to stems.

Dr. Ranke observes, in the conclusion of his paper, that the similarity which has been established between animal and plant electricity warrants us in applying to the latter, with certain modifications, Du Bois Reymond's molecular hypothesis of animal electricity. We may suppose the interior of electromotive parts of plants filled with small peripolar molecules embedded in a conducting substance, the axes of these (joining the poles of each molecule) being parallel to the axis of that part of the plant containing them. The theory of animal electromotors supposes each of the molecules to have two negative polar zones, and one positive equatorial. The law of plant electricity requires, on the other hand, for each of the molecules, two positive polar zones and one negative equatorial.

A. B. M.

MINERALOGY.

A COURSE of six lectures on the above subject is in course of delivery to working men only at the Geological Museum on Monday evenings, by W. W. Smyth, F.R.S., Lecturer on Mining and Mineralogy at the Royal School of Mines. The first lecture was delivered on Monday, Nov. 11th, and dealt principally with definite geometrical forms assumed by inorganic substances.

These, he said, are extremely multifarious and varied; but, as they are intimately connected with the internal structure of the substances, and with their optical and other properties, it becomes very necessary to make ourselves acquainted with the laws governing these forms if we would rightly understand the substances themselves. Some observations on these forms were made by the Ancients, but they never appear to have been led to generalise on the matter. An objection to the more general study of this subject is often urged in that perfect and regular crystals could only be seen and studied in large collections and in museums; but the lecturer showed that, even in this science, materials for common observation were at hand if people would only look for them. He

admitted, at the same time, however, that there is a great advantage to be derived from first studying those regular and perfect forms before advancing to less regular and less distinct ones. As an example of the common occurrence of crystals, he instanced those large white finger-like masses to be seen in the stone employed in many of our London bridges, which are often mistaken for fossils, but which are really crystals of the kind of felspar known as "orthoclase." Again, in examining a piece of common granite carefully, besides crystals like the above on a smaller scale, other crystals of a darker substance may also be seen, together with some thin leaf-like pieces of a third substance having a strong lustre. These are crystals of the materials of which granite is formed, viz., felspar, quartz, and mica. In a piece of crystalline marble may be seen also numerous bright little crystals lying in all manner of positions. In all the above cases, the individual crystals are not fully developed, because, owing to their lying so close together, they have more or less mutually interfered with each other.

If the crystals have been formed under favourable conditions, they will always assume a definite form, from whatever part of the world they are obtained. Thus, a crystal of quartz or rock crystal was shown to assume the form of a hexagonal prism, terminated by a hexagonal pyramid; a crystal of beryl to have a hexagonal prismatic form, but terminated by plane faces. And as each individual substance always assumed the same form, with certain definite limits and modifications, a knowledge of these forms must necessarily be a great help towards determining the nature of any inorganic substance. The lecturer illustrated this by referring to a fine quartz crystal on the table, brought by a Cornish miner from Brazil under the impression that it was a large diamond. The diamond always crystallises in the octahedron and allied forms. Sometimes, as in the case of carbonate of lime, the modifications of the fundamental form are very numerous, in that substance amounting to twelve hundred, but all within definite geometrical limits.

There are several possible ways of describing a crystal, e.g., the position of its faces might be referred to the walls and ceiling of a room, or of some figure surrounding them, or they might be referred to certain imaginary lines or axes drawn within them. The latter is the mode now generally adopted, and forms which are in external appearance quite distinct are capable of being grouped together by means of their axes. Thus the hexagonal prism and hexagonal pyramid agree in having a hexagonal middle section, and they both belong to a system characterised by having one upright axis and three equal horizontal axes intersecting at equal angles. By means of axes placed in certain positions, the rhombohedron, and the scalenohedron (bounded by twelve scalene triangles) might be referred to the same group. Similarly with the group to which the octahedron belongs (and of which that form is taken as the basis) in which the axes are all equal. If we imagine a triangular pyramid erected on each face of the octahedron, we shall get a figure with twenty-four faces, technically called the triakis-octahedron. The cube is derived from the octahedron by imagining a plane in each angle of that figure parallel to the two axes not belonging to that angle.

According to this method of grouping together crystals according to their internal axes, six groups or systems are distinguished:—

(a). *Cubical System*.—To which the cube and octahedron belong. Has three equal axes intersecting at right angles, one regarded as vertical, and the other two as horizontal.

(b). *Hexagonal or Rhombohedral System*.—Has one vertical and three horizontal axes, the latter making equal angles with each other and being equal among themselves, but shorter or longer than the vertical.

(c). *Pyramidal or Tetragonal System*.—Has axes like the cubical system, with the exception that its vertical axis varies in length, being sometimes longer and sometimes shorter than the horizontal ones.

(d). *Rhombic or Prismatic System*.—All its axes are unequal, though, like (a) and (b), intersecting at right angles.

(e). *Oblique System*.—Characterised by three unequal axes, two in the same plane at right angles to each other, the third oblique to that plane.

(f). *Doubly Oblique System*.—In this all the axes are of unequal length, and make unequal angles with each other.

Under one or other of these groups of forms may be classed, not only all the crystallised substances found in nature, but also those artificial crystals produced in the laboratory of the chemist.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 21st, 1872.

DR. FRANKLAND, F.R.S., &c., President, in the Chair.

THE minutes of the previous meeting having been read and confirmed, the names of Messrs. Alfred Payne, George Combe Stewart, Robert Routledge, and George B. Beilby were read for the first time; and for the third time, Messrs. Arthur Willis and George Symington Grieve Paton, who were balloted for and duly elected.

The first paper, "On the Standardising of Acids," by W. N. HARTLEY, F.C.S., was read by the Secretary. Instead of the sodium carbonate usually employed for this purpose, the author prepares a solution of pure sodium hydrate from a block of metallic sodium cut from a bar of that metal, and which is weighed in a capsule made from two test-tubes having their lips cut off and inverted one within the other. The sodium is dissolved in alcohol and then diluted with water; as the strength of the solution thus obtained is known, it may be at once employed for standardising the acid.

Dr. FRANKLAND, in thanking the author in the name of the Society, remarked that everyone who had worked with standard solutions of acids had experienced the difficulty there was when employing sodic carbonate, owing to the carbonic anhydride preventing that sharp recognition of the point of neutralisation which was obtained when a solution of caustic alkali was used.

The next communication, "On Anthraflavic Acid," was read by the author, Mr. W. H. PERKIN, F.R.S., &c. After alluding to his former paper on the same subject, in which he had expressed his opinion that anthraflavic acid was an isomer of alizarine, a view since confirmed by Auerbach, he stated that, when anthraflavic acid is strongly heated, it yields a golden yellow sublimate having the properties and composition of the original substance, and that the product obtained on fusing anthraflavic acid with alkalis, and which Schunck supposed to be alizarine, produces very different shades with alum mordants from those obtained with the latter colouring matter.

On heating the acid with acetic anhydride to 160°, a new compound, *diacetyl-anthraflavic acid*—

is obtained, which crystallises in very pale yellow plates, not unlike benzoic acid in shape, and which melt at about 228°. The corresponding *diacetyl-alizarine*, prepared in a similar manner from alizarine, crystallises in flat needles or plates, which melt at about 160°, and are more soluble in alcohol and glacial acetic acid than *diacetyl-anthraflavic acid*. Anthraflavic acid, treated with benzoyle chloride, yields *di-benzoyl-anthraflavic acid*—

a crystalline substance, of a pale yellow colour, which fuses at 275°. It would appear from the researches of Liebermann and Auerbach, that not only does anthraflavic acid occur as a by-product in the manufacture of artificial alizarine, but another substance, *monoxanthraquinone*, $\text{C}_{14}\text{H}_7\text{O}_2\text{HOO}$, differing from it in being readily soluble in baryta water.

The PRESIDENT said he was sure the Members would agree with him in thanking their Secretary for the additional information he had given them on the subject of anthraflavic acid, although he questioned how far we were justified in calling the compound an acid, as, when the basic hydrogen is replaced by acetyl or benzoyl, it yields compounds which do not possess the properties of anhydrides, as they should do if it were a true acid.

Mr. PERKIN replied that he regarded the hydrogen as being more of an alcoholic nature, and that he had merely retained the name of anthraflavic acid originally given to it by Dr. Schunck.

Dr. DEBUS asked whether the author could suggest any rational formula for the substance, or any combination of atoms which would show the nature of the substance.

Dr. ARMSTRONG observed that it was probable that the sulpho-acids obtained from anthracene for the preparation of alizarine were a mixture of isomeric acids, from one of which the anthraflavic acid was derived. Naphthalene and phenol, as is well known, yield isomeric sulpho acids.

Mr. PERKIN replied that the sulpho acids employed were certainly a mixture—both mono and disulpho acids were present, and probably also isomeric forms of the latter; but as yet he had not any process by which the anthraflavic acid could be directly prepared.

In reply to some observations by Dr. DEBUS on the internal movement of atoms which takes place when isomeric bodies change one into the other, Dr. ARMSTRONG remarked that, if this were the case, the change of place amongst the carbon atoms must be most extraordinary in some instances. For example, in the butylic series the alcohol—

when converted into the corresponding butylamine, and then into the nitrate, yields the secondary alcohol—

and from this, again, by a similar process, we obtain the tertiary alcohol—

These changes, however, pointed to a method of great importance by which it was probable we might generate many new compounds. Each of these butylic alcohols had a lower boiling-point than that from which it was derived. Might not the amylic alcohols, if treated in a similar manner, yield the whole series?

Dr. DEBUS said that, if an organic compound went through a series of changes, it was assumed that the end product contained the same nucleus as that from which we originally started. Although this was generally true, it was not by any means a universal proposition, for there was a strong body of evidence to show that the nucleus sometimes underwent change.

The PRESIDENT said, the supposition that the atoms do not move in a compound must be received with caution, although it was true that some organic compounds might be treated with the most powerful reagents, and still retain their original form. The amylic alcohol, which causes a deviation of the plane of polarised light, was of this class; even boiling with sulphuric acid and acid potassic chro-

mate did not cause it to lose this property, which was also possessed by all its compounds, so that we may assume it does not change, as its effect on light remains the same.

Dr. ARMSTRONG remarked that the sulpho acid produced by treating it with sulphuric acid, and yielding the gummy barium salt, had no effect on polarised light.

Professor WILLIAMSON said that, in the present state of our knowledge, certain facts seem to establish a change in the nucleus which had hitherto been deemed impossible; and he agreed with Dr. Debus that, although there are numerous instances in which the nucleus is not affected, we now and then come across one in which a change appeared to take place, and the number of these was rapidly increasing.

Dr. DEBUS said that, when we consider inorganic compounds, we find great mobility amongst the atoms; but this was not the case with organic substances, in which the carbon atoms seemed to be so locked together, as it were, that there was no freedom of motion amongst them, and this property was extended to the other elements, such as chlorine and hydrogen, with which they happened to be in combination. For instance, sodium chloride gives a precipitate of argentic chloride with silver nitrate, but carbon chloride dissolved in alcohol does not give argentic chloride with silver nitrate, neither do the alcoholic chlorides, like chloride of ethyl. Under certain circumstances, however, such as increase of temperature, the force which held the atoms together became weakened, so that they became able to move with greater freedom and arrange themselves in new positions, forming new combinations.

Dr. WILLIAMSON desired to call the attention of the Members to a case of this which was well known to them all, that of bitter almond oil, a well defined and undoubted aldehyde, which, under the influence of alcoholic potash, split up into benzylic alcohol and benzoic acid. We are too prone to forget these well-established cases of change of position, and allow them to escape our notice. The fixity of carbon in organic compounds was unparalleled amongst inorganic compounds, and in this respect quite exceptional.

Dr. FRANKLAND said that, in these internal movements of the atoms, the great matter of surprise was that the carbon atoms should change their places, and not that the other elements should do so.

The meeting then adjourned until Thursday, December 5th, when there will be two papers by Professor C. Rammelsberg, "On the Reducing Power of Phosphorous and Hypophosphorous Acids and their Salts," and "On Hypophosphites; also a paper "On New Analyses of some Mineral Arsenites and Phosphates," by Professor A. H. Church.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 29th, 1872.

EDWARD SCHUNCK, Ph.D., F.R.S., Vice-President, in the Chair.

Dr. R. ANGUS SMITH, F.R.S., described a remarkable fog which he saw in Iceland. It appeared to rise from a small lake and from the sea at about the same time, when it rolled from both places and the two streams met in the town of Reykjavik. It had the appearance of dust, and was called dust by some persons there at first sight. This arose from the great size of the particles of which it was composed. They were believed to be from $\frac{1}{1000}$ th to $\frac{1}{100}$ th of an inch in diameter. They did not show any signs of being vesicular, but through a small magnifier looked like transparent concrete globules of water. They were continually tending downwards, and their place was supplied by others that rolled over.

Ordinary Meeting, November 12th, 1872.

J.P. JOULE, D.C.L., LL.D., F.R.S., &c., President, in the Chair.

Charles Anthony Burghardt, Ph.D., and Henry Arthur Smith, F.C.S., were elected Ordinary Members of the Society.

"An Account of some Experiments on the Melting-Point of Paraffin," by B. STEWART, F.R.S.

The following experiments were made with the view of ascertaining—

- (1). Whether the melting-point of different specimens of paraffin is the same.
- (2). Whether that of the same specimen remains the same.

The method of observation adopted in these experiments was as follows. The thermometer had its stem fitted into the cork of a colourless glass flask so that when the flask was corked the bulb was in the centre of the flask, the extremity of the mercurial column appearing during the experiment slightly above the cork. The flask was kept heated to a point slightly below that of the melting-point of paraffin. The bulb of the thermometer was then dipped for a few seconds into some melted paraffin a few degrees above its melting point, and while covered with a fluid coating of paraffin was replaced in the centre of the flask. The flask being only a very little colder than the bulb, the cooling was then very slow.

The instrument was placed so that the reflected image of the bar of a window was seen distinctly in the mercury of the bulb through the liquid paraffin. One observer carefully scrutinised this reflected image by a lens, while another watched the downward progress of the column of mercury in the stem of the thermometer. As soon as the observer scrutinising the image observed a want of definition produced by incipient freezing, he noted the circumstance to his colleague watching the column, and thus the exact reading at which freezing began was ascertained. It was found easily possible to ascertain this point to one-tenth of a degree Centigrade. Four or five separate observations were generally taken, before each of which the thermometer was re-dipped into the melted paraffin.

In case of any change taking place in the zero of the thermometer while the experiments were in progress, the instrument was tried in melting ice before each experiment. The thermometer employed was a standard, constructed at Owens College, No. 3.

The coating of paraffin surrounding the bulb was sometimes kept from one experiment to another, being always carefully dried after the bulb was plunged in melting ice, and sometimes it was removed, but this circumstance did not appear to affect the results.

It was soon seen that different specimens of paraffin had very different melting-points, so that the research was directed to the second question, namely, whether the same specimen retains the same melting-point, after being frequently melted and solidified.

The following is a record of the various experiments made;—

1872.		Paraffin melted at 45°05.	
Feb. 29	..	"	" (thermometer not observed).
Mar. 6	..	"	" at 44°90.
" 13	..	"	" (thermometer not observed).
" 21	..	"	" at 44°90
" 26	..	"	" (thermometer not observed).
April 11	..	"	" (thermometer not observed).
" 19	..	"	" at 45°00.
" 26	..	"	" (thermometer not observed).
May 3	..	"	" at 45°00.
" 10	..	"	" (thermometer not observed).
" 16	..	"	" at 45°00.
" 23	..	"	" (thermometer not observed).
June 1	..	"	" " "
" 6	..	"	" " "
" 13	..	"	" at 44°90.

The paraffin was melted without an observation of the thermometer at the following dates—June 19, 27; July 3, 19, 25; Aug. 1, 9, 16, 22, 31; Sept. 6, 14, 21, 27; Oct. 8, 17.

Observations with the thermometer were then resumed with the following results:—

Oct. 24 .. Paraffin melted at 44°60.
" 31 .. " " (thermometer not observed).
Nov. 7 .. " " at 44°70.
" 11 .. " " at 44°75.

The experiments now described have been made chiefly by Mr. F. Kingdon, assistant in the Physical Laboratory of Owens College. The most probable conclusion to be deduced from them appears to be that the melting-point of this specimen of paraffin has become somewhat lowered since the experiments began.

It is proposed to continue these experiments for some time longer; but in the meantime it has been thought desirable to describe the method of research, as this may be of interest to observers of melting-points.

CORRESPONDENCE.

MANUFACTURE OF SOAP.

To the Editor of the Chemical News.

SIR,—Kindly allow me space for a few remarks with reference to the paper on "The Analysis of Soaps" (CHEMICAL NEWS, vol. xxvii., p. 207), by Mr. J. Jean.

This gentleman makes a great mistake in classing resin amongst the fraudulent adulterations of soaps. Its employment in certain kinds is, beyond cavil, clearly insisted upon by the greatest number of consumers of the article. They will have soap so made, and no other. Enquiry of any one merely acquainted with the routine of a Soapery will suffice to prove this. Moreover, as I have been intimately associated with the practical details of the manufacture for twenty years past, I am enabled to add that this requirement as regards resin is simply a matter of fact. The demand for pale or yellow soaps—an indispensable feature of which is that they must contain from one-fourth to about one-third of resin—has existed for about a century past; and the call for these sorts, so far from diminishing, continues steadily on the increase.

In conclusion, allow me to add that about two years ago I solved the somewhat knotty problem as to the determination of the amount of resin in admixture with fatty matters in such soaps. This I can always effect in about one hour. Almost all the leading soap-manufacturers in England have been for some time in possession of the method, which I have only disclosed under a secret arrangement.—I am, &c.,

ALFRED G. ANDERSON,
Professor of Practical Chemistry in
Queen's College, Birmingham.

146, Ladbroke Grove Road, North Kensington, W.,
November 26, 1872.

ODOURS OF PLANTS.

To the Editor of the Chemical News.

SIR,—I much appreciate Mr. Robert Mallet's remarks in your issue of the 15th inst. upon my previous brief communication concerning the "Utility of Odours to Plants in relation to Radiant Heat," but cannot quite understand whether the views to which he courteously refers as coinciding with my own were expressed only verbally or in manuscript to Professor Tyndall, or were published in any of the scientific journals. If the latter were the case, perhaps Mr. Mallet will kindly intimate in which of those periodicals they appeared.

Permit me also to observe that, although the question of quantity or "how much" is, as Mr. Mallet has remarked, an important one in most scientific speculations, still inability strictly to answer it does not always invalidate, or materially affect, our conclusions. In the case of odorous vapours, it must, too, be remembered that we are contemplating matter in, to us, an *imponderable* form, and that, therefore, any inferences relative to mere quantity must be extremely problematical.

I would, moreover, remind Mr. Mallet that, so far from the air in Professor Tyndall's experimental tubes having been "saturated in an odorous vapour," it was merely allowed to pass once over bibulous paper wetted with the different perfumes referred to in the lecture, and consequently the amount of the vapour taken up by it must, we may fairly conclude, have been as "infinitesimally small and unweighable as that which is sufficient to diffuse the perfume of the flower or fruit."

Perhaps the comparative loss of odour, mentioned by Mr. Mallet, in "the orange orchards of the South," may be attributable to the greater dryness of the air in those latitudes, and the consequent want of the great carrier of of vegetable odours—aqueous vapour.

If, however, the odour emitted be absolutely less in this and similar cases, the "heat jacketing" effects, on account of a higher atmospheric temperature, may be less needed by the plants in those regions.

Begging to thank you for the insertion of my preceding very imperfect observations,—I am, &c.,

W. H. OLLBY.

Stoke Newington, November 23, 1872.

MISCELLANEOUS.

The Chemical Professorship at Cambridge.—We are informed that Mr. J. Alfred Wanklyn has applied for this appointment. In the interest of Science we should be glad to see Mr. Wanklyn holding a chemical appointment.

London and General Water Purifying Company.—During the recent absence of H.R.H. the Prince of Wales from Sandringham, the London and General Water Purifying Company received orders to apply their system of filtration throughout the establishment, which they completed on Saturday last. It may therefore be considered that the danger arising from the former impurity of the water is now removed.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 18, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Shape to be Given to the Standard Meters which the International Committee for Weights and Measures is about to get Constructed.—M. Tresca.—The author explains at length the reasons why the Committee determined to give to the standard meters a shape somewhat resembling an X; this shape exhibits by the smallest bulk of metal the greatest resistance, which exceeds 30 kilos. to the square millimetre; the lines indicating the divisions of the meter are to be engraved between the branches of the X.

Researches on the Natural Production of Nitrates and Nitrites; Application of Mineral Manure to Horticulture.—J. Jeannel.—Reserved for full translation.

Researches on Liquid Carbonic Acid.—L. Cailliet.—After briefly referring to Thilorier's researches on the liquefied carbonic acid gas (which boils at -78° at atmospheric pressure), the author describes his apparatus for experimenting with this fluid, which is colourless, very mobile, and a non-conductor of electricity; it neither dissolves common salt, sulphate of soda, chloride of calcium, nor carbonate of potassa, which is converted into bicarbonate insoluble in the fluid; carbonate of lime, either in the form of Iceland-spar or chalk, is not dissolved by this fluid, even under a pressure of 130 atmospheres (1950 lbs. to the square inch). Sulphur and phosphorus are insoluble in liquefied carbonic acid, but iodine is somewhat soluble therein; water scarcely dissolves the fluid, but ether and petroleum oil dissolve it readily, and sulphide of carbon dissolves it to some extent. Fatty oils are somewhat soluble in the liquefied carbonic acid, but stearine and paraffin are insoluble therein.

New Native Silver Amalgam from Kongsberg, Norway.—F. Pisani.—Reference is first made to the hitherto-known, and mineralogically described, native amalgams of silver. The two varieties of the mineral investigated by the author are crystalline; one has a dull silver-white colour, the other a light brass-yellow. The first variety was found to contain, in 100 parts, 95.26 of silver, and 4.74 of mercury; the other, 94.94 of silver, and 5.06 of mercury. On further investigation of a sample of native crystalline silver from the same locality, the author found that it also contains mercury, but in larger quantity, viz., 13.7 per cent, and 86.3 per cent of silver; formula, Ag_4Hg .

Action of Sulphurous Acid on Recently-Precipitated Insoluble Sulphurets.—A. Guérout.—This essay treats at length on the action which sulphurous acid exerts upon the recently-precipitated metallic sulphurets. It appears that whereas some of these are quite insoluble in this acid (viz., the sulphurets of copper, silver, gold, platinum, and mercury), others are dissolved, but this is attended by the formation of hyposulphite, and is the result of the three following successive reactions:—(1) Formation of a sulphite and of sulphuretted hydrogen; (2) decomposition of the sulphuretted hydrogen and the sulphurous acid, with formation of sulphur and water; (3) combination of the nascent sulphur with the sulphite.

Tooth of the Elephas Primitivus Found by M. Pinard in Alaska, North America.—A. Gaudry.—The locality where the tooth was found is situated at 59° N. lat. and 156° 41' W. long. from Paris. The contents of this paper bear mainly upon palæontology; the analysis of the tooth proved it to contain, in 100 parts—Mineral matter, 64.05; organic matter, 23.97; water, 11.98. The author observes that this tooth (although a genuine fossil) contains nearly as much organic matter as that contained in the teeth of living elephants; usually the quantity of organic matter met with in such fossil remains or in bones does not exceed 3 per cent.

This number again contains memoirs on fermentation. Among the papers not relating to chemistry we call attention to an important memoir:—

Theory of the Production of Animal Heat.—Dr. Bouillard.

The American Journal of Science and Arts, November, 1872.

This number contains no original papers relating to chemistry.

La Revue Scientifique de la France et de l'Etranger,
November 25, 1872.

This number contains no papers relating to chemistry, but we call attention to an exhaustive memoir:—

The Cattle Plague, Luesbovina.—M. Bouley.—This essay contains important information on the antiquity, origin, and propagation of the disease, and also on the best means of preventing its increase, as well as its complete extinction.

Bibliography.—Under this heading attention is called to the following works just published:—"Etudes sur le Vin, ses Maladies, Causes qui les Provoquent, Procédés Nouveaux pour les Conserver et le Vieillir," par M. L. Pasteur; Paris: Savy, 1872. "Éléments de Statistique," par L. Poinso, Membre de l'Institut et du Bureau des Longitudes; onzième édition, précédée d'une notice sur L. Poinso, par J. Bertrand, Membre de l'Institut; 1 vol., avec planches; Paris: Gauthiers-Villars, 1873. "Cours de Physique Mathématique," par M. Emile Mathieu, Professeur à la Faculté des Sciences de Besançon; Paris: Gauthiers-Villars, 1872.

Polytechnisches Journal von Dr. E. M. Dingler, second number for October, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Preparation of Cyanide of Mercury.—A. Lielegg.—The author describes, and illustrates with a woodcut, an improved method of preparing cyanide of mercury, by passing the vapours of anhydrous hydrocyanic acid into water in which finely-divided oxide of mercury is suspended.

Behaviour of some Metals with a Solution of Ferricyanide of Potassium.—Professor Böttger.—The metals palladium, thallium, magnesium, and arsenicum possess, according to the author's researches, the property of reducing, or converting to a lower degree of oxidation, certain saline solutions; among these are ferricyanide of potassium, converted into ferrocyanide, perchloride of iron into perchloride, persulphate of iron into protosulphate. If, into a solution of 5 decigrams of ferricyanide of potassium in 100 c.c. of distilled water,

a piece of palladium-foil is placed for ten minutes, daylight being excluded, it will be found, on testing this solution with a peroxide salt of iron, that the ferricyanide has been converted into ferrocyanide. Platinum, zinc, cadmium, aluminium, copper, indium, lead, cobalt, silver, mercury, tin, bismuth, antimony, tellurium, gold, manganese, and iron, have no action on the solution.

Analysis of the Commercial Red Phosphorus.—Drs. R. Fresenius and E. Luck.—It appears that this substance contains on an average a total percentage of 92.63 of red or amorphous phosphorus, 0.56 of yellow phosphorus, 1.308 of phosphorous acid, 0.88 of phosphoric acid, and 4.622 of water. The phosphorus is oxidised by nitric acid, and the phosphoric acid estimated as pyrophosphate of magnesia; the yellow phosphorus is eliminated from the mass by means of sulphide of carbon.

Journal de Pharmacie et de Chimie, November, 1872.

In addition to several papers relating to pharmaceutical science, this number contains the following original paper bearing upon chemistry:—

Explosive Property of a Mixture of Nitrate of Potassa and Acetate of Soda.—M. Violette.—It appears that the author, while heating a mixture of nitrate of potassa and acetate of soda in a small glass flask, was seriously injured by a sudden and violent explosion of the substances he operated upon. This accident gave rise to further investigation, the result of which is that a mixture of 100 parts of nitrate of potassa and 60 of acetate of soda, when heated and fused at about 300° , do not explode, and may even, after cooling, be pulverised and granulated; but if the salts are heated to 350° , or ignited by means of red-hot iron, a violent explosion instantly takes place. When either the nitrate or acetate is in excess of the quantity mentioned, the mixture only burns as dry wood would do.

Les Mondes, November 21, 1872.

This number does not contain any original matter relating to chemistry.

Bulletin de la Société Chimique de Paris (double number), October 1 and 15, 1872.

This number contains the following original papers and memoirs:—

Compounds of Yttrium and Erbium.—P. T. Clève and C. Hoeglund.—This second instalment of an exhaustive memoir is elucidated by a large number of complex formulae; it treats mainly on the salts and double salts of the metals. Most of the salts of yttrium and erbium contain the same quantity of water of crystallisation as the corresponding salts of magnesium and zinc; the sulphates are isomorph with the sulphate of cadmium, and the platinocyanides crystallise in the same form as the platinocyanide of magnesium. The authors have not isolated the metals (erbium and yttrium), but from many of their combinations they appear to be triatomic. No analytical method of separating the metals just named from each other has been found by the authors, but it is easy to deduct from a mixture of known weight of their oxides the atomic weight by the following formula:—

$$\text{ErO} = 240.19 \frac{\text{MO} - 75.7}{\text{MO}}$$

The atomic weight of the oxides obtained from the following minerals has been found by Clève to be—

	Atomic Weight.	Percent of Oxide of Erbium.
Fergusonite from Ytterby	90.54	39.37
Nohlite from Kongelf	84.80	25.77
Euxenite from Arendal	90.62	38.97
Ytrotantalite from Karafuelt	80.08	13.14

Solvent Property of Glycerin.—M. Klever.—100 parts of glycerin dissolve the following substances in the following proportions:—Carbonate of soda, 98; borate of soda (borax), 60; arseniate of potassa, 50; arseniate of soda, 50; chloride of zinc, 50; tannic acid, 50; urea, 50; alum, 40; iodide of potassium, 40; iodide of zinc, 40; sulphate of zinc, 35; sulphate of atropine, 33; cyanide of potassium, 32; sulphate of copper, 30; cyanide of mercury, 27; bromide of potassium, 25; sulphate of protoxide of iron, 25; sulphate of strychnia, 22.5; acetate of morphia, 20; acetate of lead, 20; arsenious acid, 20; arsenic acid, 20; carbonate of ammonia, 20; carbonate of soda, 20; chloride of soda, 20; chloride of ammonium, 20; chlorhydrate of morphia, 20; lactate of protoxide of iron, 16; oxalic acid, 15; acetate of copper, 10; benzoic acid, 10; boric acid, 10; chloride of barium, 10; bicarbonate of soda, 8; tartrate of iron, 8; bichloride of mercury, 7.5; sulphate of cinchonine, 6.7; tartar emetic, 5.5; polysulphuret of calcium, 5; nitrate of strychnia, 4; chlorate of potassa, 3.5; atropine, 3; brucine, 2.25; iodine, 1.9; veratria, 1; cinchonine, 0.5; quinine, 0.5; morphia, 0.45; tannate of quinine, 0.25; strychnia, 0.25; phosphorus, 0.2; sulphur, 0.1.

Quantitative Estimation of Phenol.—M. Schaefer.—The substance in which the quantity of phenol is to be ascertained is treated with concentrated sulphuric acid, which combines with the phenol (present in any sample of commercial phenol), while the impurities are carbonised by the acid. The resulting phenol-sulphuric acid is converted into a baryta salt, in which the quantity of phenol-sulphate of baryta present is estimated by the conversion of that salt into sulphate of baryta. The operation is described as follows:—2 or 3 grms. of the phenol to be tested are mixed with an equal weight of pure and strong sulphuric acid, and the mixture heated to from 50° to 60° for some

time; the mixture is next filtered with water, neutralised with carbonate of baryta, decanted, filtered, washed, and the filtrate precipitated with dilute sulphuric acid; the ensuing precipitate of sulphate of baryta is collected upon a filter, washed, dried, ignited, and weighed. 233 parts of sulphate of baryta correspond to 188 parts of phenol; the quantity by weight of sulphate of baryta found has to be multiplied the *rapporti* 188, which is equal to 0.8069.

There is added to this number a comprehensive price-list of the well-known firm of Billaut, Billandot, and Co., 24, Rue Sorbonne, Paris, of chemicals and rare chemical compounds, as well as chemical and other apparatus required for scientific research.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, July, 1872.

In addition to two essays relating to chemistry which have been already noticed by us from the *Berichte der Deutschen Chemischen Gesellschaft zu Berlin*, this number contains the continuation of the following memoir:—

On Hypophosphites.—Dr. C. Rammelsberg.—This portion is divided into the following sections:—Reducing action of hypophosphorous and of phosphorous acid; phosphorous acid and silver salts; phosphorous acid and copper salts; hypophosphorous acid and silver salts; hypophosphorous acid and copper salts; hypophosphite of ammonia; composition of fluid hypophosphorous acid.

Composition of the Black Yttrotantalite.—Dr. C. Rammelsberg.—Sp. gr. of this mineral = 5.425; per cental composition of the ignited mineral—Tantalum acid, 49.36; niobium acid, 13.15; tungstic acid, 2.52; stannic acid, 1.19; yttria, 11.03; erbia, 7.16; oxide of cerium, 2.37; lime, 6.47; protoxide of iron, 4.30; protoxide of uranium, 1.72.

Journal für Gasbeleuchtung und Wasserversorgung, No. 19, 1872.

This number contains the following original papers collaterally relating to chemistry:—

Thermostatic Gas-Regulator.—J. Jeannel.—The description, illustrated by woodcut, of an apparatus contrived for the purpose of keeping up a regular and high temperature (above the boiling-point of mercury if desired) for use in scientific research.

Oxygen-Gas Illumination Introduced by Tessié du Motay.—F. Le Blanc.—The first portion of the official report of the author, Chief Inspector of Gas-Works and Gas-Lighting in Paris, to the Conseil Général du Département de la Seine.

Mélanges Physiques et Chimiques Tirés du Bulletin de l'Académie Impériale des Sciences de St. Petersburg, Vol. viii., 1872.

This number, kindly forwarded to us by Dr. A. Boutlerow, contains the following original essays and papers:—

Trimethyl-Acetic Acid, a New Variety of an Isomer of Valerianic Acid.—Dr. A. Boutlerow.—The introductory part of this lengthy monograph is devoted to the mode of preparation of this acid, only obtainable by a complicated and difficult process of operation. Trimethyl-acetic acid—

is at the ordinary temperature a solid, semi-crystalline, diaphan body, fusing at between 34° and 35°, insoluble in water; the taste of this substance is bitter and pungent, while its smell is similar to that of acetic and valerianic acids, but not so disagreeable as the latter. The baryta salt of this acid has the formula $(\text{C}_3\text{H}_7\text{O}_2)_2\text{Ba} + 5\text{H}_2\text{O}$, and is a crystalline body readily soluble in water; it contains 40.41 per cent Ba. The silver salt is anhydrous and crystalline, much resembling benzoic acid when slowly deposited from a hot concentrated aqueous solution; formula of silver salt, $\text{C}_3\text{H}_7\text{O}_2\text{Ag}$.

On Trimethyl-Formen-Ethyl, an Isomeric Variety of Hexan.—W. Goriainow.—By causing zinc-ethyl to react upon tertiary iodide of butyl, and purifying the fluid resulting from this reaction, the author has obtained a new hydrocarbon in the shape of a colourless liquid boiling at between 43° to 48°; formula, C_6H_{14} ; vapour density—in reference to hydrogen, 43.0; in reference to air, 2.975.

Conversion of Amylen into an Amylic Alcohol by means of Sulphuric Acid.—M. Flavitsky.—After referring to the researches made by Berthelot, Erlenmeyer, and Dr. Boutlerow, relating to this subject, the author describes at length his mode of experimenting, by which amylen, prepared at the chemical works of Dr. Marquart at Bonn by the action of chloride of zinc upon ordinary amylic alcohol, has been converted into an amylic alcohol by the action of sulphuric acid; this alcohol having been converted into a chloride, $\text{C}_5\text{H}_{11}\text{Cl}$, this was found to boil at between 85° and 87°, while, by oxidation, the alcohol yielded acetone.

Action of Bromated Bromide of Acetyl upon Zinc-Methyl.—N. Idanow.—In the introduction to this memoir the author mentions a series of researches made on this subject by Terhoukassow. It appears that, by the action of bromated bromide of acetyl upon zinc-methyl, several substances are formed, among which are prominently two alcohols, $\text{C}_4\text{H}_9\text{O}$ and $\text{C}_4\text{H}_9\text{O}$, but the first-named is the chief product of the reaction. The author continues his researches on this subject, and elucidates the reaction with the following formulæ:—

Formation of Tertiary Chloride of Butyl by Means of Isobutylene.—D. Salasky.—The contents of this essay, elucidated by a series of complex formulæ, may be summarised by stating that chlorhydric acid behaves with isobutylene in the same manner as iodyhydric acid, the result being the formation of a tertiary chloride of butyl.

New Variety of Hexylen.—N. Tchaikowsky.—The author records at length the method of preparation of the hexylen alluded to, the formula of which is C_6H_{12} ; boiling-point between 68° and 72°; vapour density, in reference to air, 2.908; in reference to hydrogen, 42.0. This hexylen is a fluid substance; constitutional formulæ—

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

3032. J. Hargreaves and T. Robinson, Widnes, Lancashire, "Improvements in treating sulphides, and in obtaining products therefrom."—Petition recorded October 15, 1872.

3067. W. Morgan Brown, Southampton Buildings, London, "An improved composition for preserving wood, metal, stone, brick, paper, textile and felted fabrics, cordage, and cables."—A communication from F. O. Möller, Rue Lavoisier, Paris.—Petition recorded October 17, 1872.

3300. G. H. C. Hedley, W. Smith, and T. A. Hedley, Salisbury Street, Strand, London, "Improvements in the manufacture and purification of gas, and in the apparatus employed therein and connected therewith."

3308. M. Rae, Uphall, Linlithgow, N.B., "Improvements in the production of artificial fuel and in the machinery employed therein."

3309. H. Deacon, Widnes, Lancashire, "Improvements in the manufacture of bleaching-liquor."—Petitions recorded November 7, 1872.

3318. B. J. B. Mills, Southampton Buildings, Middlesex, "An improved process for cleansing cotton waste and fibrous substances saturated with oils and mixed with debris and other matters."—A communication from J. H. Post, New York, U.S.A.

3322. W. Marriott, Huddersfield, "Improvements in the manufacture of salts and oxides of lead, and in apparatus therefor."

3323. A. M. Clark, Chancery Lane, Middlesex, "Improvements in the manufacture of stearic acid."—A communication from E. Deise, Marseilles, France.—Petitions recorded November 8, 1872.

3335. C. de Sainte Marie, Porte Ste. Marie, France, "An improved process of tanning hides and skins."—Petition recorded November 9, 1872.

3350. H. H. Murdock, Staple Inn, Middlesex, "An improved mode of tanning hides and skins."—A communication from B. Picard, Paris.

3356. J. A. Manning, Inner Temple, London, "Improvements in the treatment of human faecal matters and in the apparatus or means employed therein."—Petitions recorded November 11, 1872.

3362. L. Banks, Kingston-upon-Hull, "Improvements in the manufacture or composition of fuel."

3371. V. D. de Michele, Delahay Street, Westminster, "Improved process for the manufacture of Portland cement, and in apparatus to be employed therein, and for other purposes."—Petitions recorded November 12, 1872.

3378. F. N. Target, Colyton, Devon, "Improvements in preserving food, and in the means or apparatus employed therein."—Petition recorded November 13, 1872.

3393. G. Clark, Drury Lane, Middlesex, "Improvements in preserving animal and vegetable articles of food, and in vessels, apparatus, and appliances for such preservation."—Petition recorded November 14, 1872.

INVENTION PROTECTED FOR SIX MONTHS BY THE DEPOSIT OF A COMPLETE SPECIFICATION.

3417. F. Hahn, Berlin, "Improvements in the manufacture of steel and malleable iron, and in furnaces therefor."—Recorded November 16, 1872.

NOTICES TO PROCEED.

2093. J. R. Casbay, Newman Street, Oxford Street, Middlesex, "An improved compound to be applied to the surfaces of wood or metal to preserve the same from corrosion or decay."—Petition recorded July 11, 1872.

2115. J. G. Tongue, Southampton Buildings, London, "Improvements in the production of fertilising materials or manures, and in the means and apparatus employed in the manufacture of the same, partly applicable to other purposes."—A communication from H. A. Hogel, New York, and H. B. Bigelow, New Haven, Conn., U.S.A.

2118. E. C. Stanford, Glasgow, N.B., "Improvements in preserving and deodorising sea-weed, and in part applicable for deodorising various animal and vegetable substances."—Petitions recorded July 13, 1872.

2205. H. A. Dufrené, Paris, France, "Improvements in concentrating and evaporating sulphuric acid and other liquids, and in the

apparatus employed therefor."—A communication from M. J. F. R. Faure and J. L. Kessler, Clermont-Ferrand, France.—Petition recorded July 24, 1872.

2510. W. Vincent, Arborfield, Berks, "Improvements in apparatus for manufacturing gas."—Petition recorded August 23, 1872.

2576. G. Spencer, Cannon Street, London, "Improvements in the purification of coal-gas used for illuminating purposes and for mechanical purposes, and in apparatus therefor."—A communication from E. White, New York, U.S.A.—Petition recorded August 30, 1872.

3231. B. F. Weatherdon, Chancery Lane, Middlesex, "Improvements in bleaching textile fabrics and other fibrous materials."—A communication from J. Palliser, R. McDowell, A. Klopsk, and V. Grumel, France.—Petition recorded October 31, 1872.

PATENTS SEALED.

1540. H. Kenyon, H. Kenyon, and J. Swindells, Warrington, Lancashire, "Improvements in the manufacture of chlorine and sulphuric acid."—Dated May 21, 1872.

1583. J. C. Johnson, Newcastle-upon-Tyne, "Improvements in the manufacture of Portland and other cements."—Dated May 23, 1872.

1608. J. H. Selwyn, Gloucester Crescent, Hyde Park, Middlesex, "A new method of treating refractory ores of silver."—Dated May 27, 1872.

1699. J. T. Dann, North Brixton, Surrey, "Improvements in the manufacture of phosphorus."—A communication from G. F. Féron, Rouen, France.—Dated June 5, 1872.

1779. R. McFarlane, Rickmansworth, Herts, "Improvements in treating wood for the production of paper pulp, and in the apparatus employed therefor, parts of which improvements are applicable to the making of steam-tight joints for various purposes."—Dated June 12, 1872.

2277. E. P. H. Vaughan, F.C.S., Chancery Lane, Middlesex, "Improvements in the treatment of phosphates of lime."—A communication from A. Striedter, Paris, France.—Dated July 30, 1872.

2318. J. Henderson, New York, U.S.A., "Improvements in converting cast-iron into steel and wrought-iron, and purifying cast-iron for foundry and other purposes."—Dated August 3, 1872.

2358. T. Warrea, Glasgow, N.B., "Improvements in and connected with furnaces employed in the manufacture of glass."—Dated August 8, 1872.

2861. C. W. Siemens, Great George Street, Westminster, "Improvements in the process for the production of iron and steel, and in furnaces or apparatus employed for that purpose."—Dated September 28, 1872.

NOTES AND QUERIES.

Tables of Acids.—Will you kindly let me know the best publication for tables of all the acids diluted, at different strengths, with water?—C. H. H.

Salt.—In reference to salt,—Was the salt mentioned in the Bible NaCl? When Christ said, "Salt is good, but if the salt has lost its savour," &c., what loss or decomposition (if any) is referred to? From the above we should suppose that another salt has been formed. Mr. Maundrell, in the "Valley of Salt, Gebul," says he "broke a piece that had been exposed to the sun and air; though it had the sparkling of salt, yet it had lost its savour; the inner part, which had not been exposed, still retained it." Can you inform me what change takes place, and what brings it about?—S. T. S.

The Reduction of Argentic-Nitrate by Organic Matter.—In January last I placed some crystals of pure argentic nitrate in writing paper, and placed it in a card-box in a cupboard. On opening the paper, which was turned quite black, a few days ago, the AgNO₃ was found to have been reduced entirely to the metallic state. It had not fallen to a powder, but was bright and crystalline.—C. T. K.

MEETINGS FOR THE WEEK.

MONDAY, Dec. 2nd.—Medical, 8.

TUESDAY, 3rd.—London Institution, 4.

Civil Engineers, 8.

Zoological, 8.30.

WEDNESDAY, 4th.—Society of Arts, 8.

Geological, 8.

Microscopical, 8.

Pharmaceutical, 8.

THURSDAY, 5th.—Royal, 8.30.

Chemical, 8. M. C. Rammelsberg, "On the Reducing Power of Phosphorus and Hypophosphorous Acids and their Salts," and "On Hypophosphites."

Mr. A. H. Church, "New Analyses of some Mineral Arseniates and Phosphates."

Royal Society Club, 6.

Philosophical Club, 6.

FRIDAY, 6th.—Geologists' Association, 8.

TO CORRESPONDENTS.

D. C.—Your first question is a geological—not a chemical—one your second and third questions may be answered by reference to a work on Chemistry or Chemical Technology.

J. Boss.—You will find works on the subject at the Patent Office Library, Chancery Lane.

BOOKS RECEIVED.

Powness' Manual of Chemistry. Edited by Henry Watts, B.A., F.R.S. Eleventh Edition. London: J. and A. Churchill.

Introduction to Inorganic Chemistry. By W. G. Valentini, F.C.S. London: J. and A. Churchill.

The Post-Office Directory of Chemists and Druggists, including Chemical Manufacturers, Wholesale Druggists, Drysalter, and Patent Medicine Vendors, of England, Scotland, and Wales. London: Kelly and Co.

The Chemists and Druggists' Diary and Pharmaceutical Text-Book for 1873. London: Office of Chemist and Druggist, 44A, Cannon Street.

A Practical Treatise on Pure Fertilisers. By Campbell Morfit, M.D., F.C.S. London: Trübner and Co.

What to do in Disinfection, and how to do it. Manchester: Mudie's Disinfecting Company.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The LABORATORY will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

THE CHEMICAL NEWS.

VOL. XXVI. No. 680.

ON THE SULPHUROUS IMPURITY IN COAL-GAS.*

By A. VERNON HARCOURT, F.R.S., Sec. Chem. Soc.

THE luminous flames we use to light our houses after sunset are all equally gas flames.

The gas which burns round the wick of a candle is formed by the action of heat on the grease of which the candle is made. The gas which burns over the wick of an oil lamp is formed by the action of heat on the oil. The gas which burns over a "gas-burner" is formed by the action of heat on coal.

By the heating of any of these substances many different kinds of gas are produced, some of which become liquids if they are allowed to cool, while others are permanently gaseous. In the case of candles and lamps, when the hot gas is burnt as fast as it is made, the uncondensable and the condensable are burnt alike, the latter contributing even more than the former to the luminosity of the flame. In the case of coal-gas, which is kept for many hours, and has often to travel along many miles of iron piping before it is burnt, only very little condensable gas reaches the burner. In this respect "gas" illumination is at a great disadvantage as compared with candles or lamps. To counterbalance this disadvantage gas must be produced from some substance which is much cheaper than grease or oil, and such a substance we have in coal. But coal, like all minerals obtained on the large scale, is mixed with small quantities of other substances, and, in particular, masses of coal always contain a greater or less proportion of a mineral known, according to its form, as pyrites or marcasite, composed of 8 parts of sulphur united with 7 of iron. When coal is heated, a part of the sulphur from this mineral unites with the carbon and hydrogen of the coal, and thus the illuminating gas formed from coal is contaminated with at least two sulphur compounds—carbon bisulphide and hydrogen sulphide. Such gas yields when it is burnt, in addition to water and carbon dioxide, sulphur dioxide produced by the burning of the sulphur. This gas has a well-known pungent smell; it acts on various colouring matters, and it is gradually changed in presence of air and moisture into a far more destructive substance, called hydrogen sulphate or oil of vitriol. Unlike sulphur dioxide, which is a gas and can be removed by ventilation, hydrogen sulphate is not volatile, and exercises a continued corrosive action upon organic materials or fabrics on which it is deposited. In a furnished room the leather bindings of books and coverings of furniture are especially liable to be injured thus; perhaps because this material, being a better conductor of heat than others which are used for the same purposes, is more bedewed after gas has been lighted in a room than they are, and also because it requires less often to be cleaned or renewed. Fortunately the conversion of sulphur dioxide into hydrogen sulphate takes place so slowly that in a room lighted with gas and well ventilated a very small part of the sulphur which gas is liable to contain remains in this destructive form. Fortunately, also, the quantity of sulphur which gas as at present manufactured is liable to contain is very small. In a room lighted with four gas-burners the volume of sulphur dioxide mixed with the atmosphere of the room in the course of an hour is about one-hundredth of a cubic foot. The amount actually present at any moment, if the room is fairly ventilated, is a small fraction of this volume. Nevertheless, it is possible, and even probable, that some injury, especially to the bind-

ings of books, may in the course of years be caused under these circumstances; and it is desirable, with a view to avoiding any such injury, and also with a view to allaying the apprehension of it, that the proportion of sulphur compounds in coal-gas should be reduced as far as possible.

A ton of coal may contain about 30 lbs. of sulphur: it yields nearly 10,000 cubic feet of gas, and a considerable part of the sulphur contained in it is given off with the gas in combination with either carbon or hydrogen. Of these two elements, hydrogen claims by far the larger proportion, not less than 10 parts for 1 that is united with carbon. For the purification of gas from hydrogen sulphide, excellent methods are everywhere in use. The gas is passed through layers of slaked lime or of iron oxide, by either of which substances all the hydrogen sulphide is capable of being completely absorbed. But the smaller quantity of sulphur existing in the form of carbon bisulphide is not arrested by these agents, nor is there at present any material or process known by which it can be effectually removed.

When coal-gas which is pure from hydrogen sulphide is heated and tested again, it is found to contain this impurity, showing that some ingredients of the gas are capable of producing hydrogen sulphide by their mutual action. Hydrogen seems to have a much stronger affinity for sulphur than carbon has. One consequence of this difference is the unequal partition of the sulphur between the two elements in the gas retort. But this inequality does not reach its limit in the short time which elapses between the formation and cooling down of the gas; and accordingly, when foul gas (or gas which has not been purified from hydrogen sulphide) is further heated, the proportion of hydrogen sulphide in it is increased, and that of carbon bisulphide diminished. From a number of experiments in which foul gas was passed through an iron tube 3 inches in diameter, filled with iron turnings and heated for a length of about 2 feet to low redness, it appeared that the amount of carbon bisulphide could be so far reduced that the gas, after purification from hydrogen sulphide, contained 5 or 6 instead of 30 grains of sulphur in 100 cubic feet. The gas was driven through the heated tube at a rate of from 1 to 2 cubic feet a minute.

A somewhat greater reduction in the amount of sulphur is obtained by heating the gas after, instead of before, purification and purifying it a second time. If it is the case, as seems probable, that the sulphur present in coal-gas distributes itself when the gas is heated between the carbon and hydrogen in a ratio dependent upon the relative affinity for sulphur of the two elements, the proportion of carbon bisulphide to the total sulphur in the gas will be always the same when the composition of the gas is the same, and when it has been heated long enough for the establishment of an equilibrium. Accordingly we should expect the removal of sulphur, by the conversion of carbon bisulphide into hydrogen sulphide and the absorption of the latter, to be accomplished more effectually with gas from which the chief part of the sulphur had already been extracted. And this, as has already been stated, is found to be the case.

The nature of the chemical change which takes place when coal-gas is heated may be illustrated by passing hydrogen over the mouth of a tube containing carbon bisulphide, and thence through a piece of combustion tubing heated nearly to a red heat. The mixture of hydrogen and carbon bisulphide vapour has no action on a solution of lead acetate; but, after the application of heat, the gas which issues produces at once a black precipitate, proving that hydrogen sulphide has been formed. This change occurs readily with hydrogen which has been carefully dried; but the presence of moisture appears to promote it; and as coal-gas contains a quantity of aqueous vapour, much more than sufficient to react with the maximum amount of carbon bisulphide, it is possible that the formation of hydrogen sulphide when coal-gas is heated may be partly due to the intervention of moisture.

If clean iron nails are heated to redness in a glass tube,

* Read before the Royal Institution of Great Britain.

and coal-gas is passed slowly over them, a soft black carbonaceous deposit is formed, and the gas is deprived of a part of its carbon. If, however, the gas be passed through more rapidly, no such deposition takes place, although the time of contact of the gas with the heated surface is still sufficient to effect the conversion of the carbon bisulphide into hydrogen sulphide. In the latter case it may be presumed that no change occurs in the illuminating power of the gas. But to establish a point which is of capital importance, some direct observations were made on the illuminating power of gas thus treated. It was found with gas passing at the rate of 5 cubic feet an hour through a half-inch iron tube, heated for a length of 12 inches, that, when the heat did not exceed low redness, no change was observable. When the heat was raised to bright redness, there was a perceptible increase in the illuminating power.

If the process of heating coal-gas, in order to remove the sulphur contained in it, should be employed on the manufacturing scale, the rate of transmission of the gas through the heating apparatus would necessarily be such as to render any deposition of carbon very unlikely. But even where such deposition takes place, it is not necessarily accompanied by a diminution of the illuminating power.

An interesting experiment, from this point of view, is the decomposition of marsh-gas by the electric spark. When a stream of sparks from a Ruhmkorff coil is transmitted between the ends of platinum wires through a small quantity of marsh-gas enclosed in a glass tube over mercury, the gas gradually expands. In about ten minutes it is nearly doubled, and at the same time a black deposit appears on the tube, in the neighbourhood of the wires. Here the intense heat applied has effected an almost complete decomposition of the hydrocarbon into its elements. But at the same time there is found a small quantity of some more condensed hydrocarbon, probably acetylene. On expelling the gas through a jet attached to the upper end of the tube, and burning it, the flame is seen to be much more luminous than that of marsh-gas itself. The fact of which this experiment gives a striking illustration is that the illuminating power of gas depends much more upon the nature of the hydrocarbons it contains than upon the total amount of carbon. How great would be the gain to the manufacturers of coal-gas, if such an operation as this were possible on the large scale, by which the volume of gas is doubled, and its illuminating power, at the same time, greatly increased!

As far as chemistry is concerned, the simple operation of heating gas appears to offer the means of a sufficiently perfect purification. The construction of a suitable system of iron pipes for heating the gas, and the best mode of obtaining and applying heat, is a problem for the engineer. On the scale on which gas is manufactured, all the apparatus for dealing with it must be of a magnitude to which it is difficult to pass, even in imagination, from the small scale of laboratory experiments; but, otherwise, the problem does not appear to be one of any peculiar difficulty. It may perhaps be found possible to employ some of the waste heat of the retort-house for this purpose, and thus to effect the required purification without much increasing the consumption of fuel.

PASSAGE OF HEAT-RAYS THROUGH INCLINED DIATHERMANOUS PLATES.

In a recent number of Poggendorff's *Annalen* Prof. Knoblauch describes some careful researches on this subject, of which we propose here to give the chief results.

The first part of his paper treats of the influence of polarisation on the phenomenon; the second, that of the nature of the plate as regards absorption.

The sun's rays were directed horizontally, by means of a heliostat, into a dark room, where they met the plate

(which was movable about a vertical axis), and, passing through it, affected a thermo-pile and galvanometer. In entering the chamber the rays passed through a Nicol's prism. The plates first employed were of colourless plate-glass, one of them 1 m.m. thick, the other 2.5 m.m. (The material of the former, in considerable thickness, looked slightly blue,—that of the latter slightly yellow).

The rays were first allowed to meet the surface at a right angle, and a certain deflection of the needle (15° , 10° , or 9°) was obtained by adjustment of a slit. The plate was next turned on its axis to a different angle.

In previous experiments with polarised heat-rays the maximum quantity of heat was found to be transmitted through diathermanous plates, when the planes of polarisation and refraction coincided, or crossed at right angles.

From the first table in the paper before us it appears (*first case*) that with the plane of polarisation horizontal, and coinciding with the refraction-plane, the quantity of heat transmitted *diminished* as the angle of incidence, or the number of plates, was increased.

On the other hand (*second case*), with the planes of polarisation and refraction crossing at right angles, the heat transmitted *increased* in quantity with increased angle of incidence and number of plates, till the angle 55° was reached (the so-called angle of polarisation); then there was gradual decrease.

For example, in the first case, when one plate was turned from 0° to 55° , the needle moved from 15° to 12° ; when eight plates were so turned, it moved from 15° to 7.5° . In the second case, on a like motion of one plate, the deflection was increased from 15° to 17° ; of eight plates, from 15° to 23.46° .

The decrease which took place in both cases after 55° was much greater in the first case than in the second.

Further, even at 60° inclination of plate in the second case, the heat produced a deflection of 16.62° for one plate, and 22.72° for eight plates, as compared with 15° when the angle of incidence was 0° .

These results were compared with others which were obtained after placing the principal section of the Nicol at 45° , instead of vertically or horizontally, the rays in this case being taken as corresponding to unpolarised rays. With this arrangement, the absorption of the glass was little affected by increasing the inclination or the number of plates, no change appearing till 35° inclination with a plate of one kind of glass, nor till 55° with one of the other; thereafter a slight decrease. With eight plates of either kind the deflection increased somewhat till 45° or 55° , after which there was decrease. Thus we have, in the present arrangement, a beginning of that which reached its maximum when the polarisation and refraction-planes crossed. The reason why this case, while between the first two, shows the approximation now referred to, is, according to Prof. Knoblauch, that the mere passage through the inclined plates calls forth a polarisation (increasingly imperfect) the plane of which is at right angles to the plane of refraction.

Another point may here be noticed. The coefficients of absorption, corresponding to changes of angle in the plate above 55° where the Nicol's principal section was vertical (and hence the two above-mentioned planes coincided), stood further apart in the case of one plate (e.g., $25 : 33$) than where there were several plates ($53 : 67$). With the principal section horizontal, on the other hand, they were nearer to each other with one plate ($4 : 9$) than with several ($11 : 56$).

To determine how, with the principal section of the Nicol horizontal (and the two planes crossing), the increased transmission of heat took place in a substance showing very little absorption of heat-rays, Prof. Knoblauch made some experiments with sylvan and rock-salt. The sylvan had a thickness of 4 m.m. (the least possible), and this was found to give too much absorption, the quantities of heat transmitted being less than with thin glass plates.

The increase of transmission, which with the glass

plates continued to 55° incidence, reached a maximum in the sylvin about 35°, which continued till 55°.

Plates of rock-salt were procured having a thickness of 1 m.m. Taking these as showing the least possible absorption of the heat-rays, Prof. Knoblauch gives a table of the results obtained, and bases on it a statement of the law in its simplest form. It is this:—

(1). With the principal section of the Nicol vertical (*i. e.*, the planes of polarisation and refraction coincident), the coefficients of absorption between 55° and 65° are smaller than between 45° and 55°, a peculiarity which, in substances somewhat absorbent of heat (as most glasses), is masked to an extent dependent on the thickness.

(2). With the principal section horizontal (*i. e.*, with planes of polarisation and refraction crossing), the transmission steadily increases till the angle of incidence becomes equal to the angle of polarisation. And when the plate is inclined beyond the angle of polarisation, decrease takes the place of increase.

(3). With the Nicol at 45°, or with unpolarised rays, the differences first commence, in the case of the rock-salt plates, at an inclination over 55°. Should this appear surprising, when compared with results from the glass and thicker rock-salt, it is to be remembered that the surface of the split lamellæ was much less perfect and favourable to diffusion of the rays than that of the plate-glass or the polished thick plates of rock-salt.

The second influence examined by Prof. Knoblauch (nature of the plate's substance) we defer for the present.

A. B. M.

ON SULPHOPHENIC ACID.*

By A. B. PRESCOTT, M.D.

THE limited observations and results which are submitted to the Association in this note, relate to a few points in the preparation, character, and composition of sulphophenic acid and its salts; and, in connection with the report, the interest of the subject has tempted the writer to notice some features of its literature.

The formation of sulphophenic acid is sufficiently simple, being the inevitable result of bringing pure sulphuric and phenic acids in contact; but we have yet to study the most advantageous proportions and conditions for the combination. If the mixture of acids be diluted beyond a certain point, no combination takes place; and when the concentrated acids act upon each other, some portion of each acid remains uncombined under all conditions. Dr. Hager has stated, that however long digestion be continued at 125° F., at least 10 per cent of the sulphuric acid refuses to combine; and he recommends the addition of 120 parts of concentrated sulphuric acid to 100 parts of phenol.

By employment of higher temperatures, I find that the residue of sulphuric acid may be reduced to about 5 per cent of that taken. 50 grms. of sulphuric acid (chemically pure, sp. gr. 1.843), were added to 50 grms. of carbolic acid (Calvert's medicinal, No. 2). The mixture was held at 300° F. for half an hour, cooled gradually with the sand-bath, and then set aside in an open vessel, at about 55° F. The mixture cooled to a thick syrupy liquid, wherein the woolly tufts shortly appeared, and at the expiration of four days, its lower four-fifths consisted of a firmly coherent crystalline mass, while the supernatant liquid was more limpid than concentrated sulphuric acid. Separate determinations of the uncombined sulphuric acid in the supernatant liquid, and of that in the crystalline mass, gave the following results:—

	Barium Sulphate.	Grms. HO.SO.
Liquid yielded	1.1710	= 0.4924
Crystals	5.1325	= 2.1584
Total		2.6508

* Read before the American Pharmaceutical Association.

As the 50 grms. of concentrated sulphuric acid contained 48.5 grms. of monohydrated acid, it appears that 5.1 per cent of the same escaped combination. Accepting the sulphophenic acid as its typical composition,—

(the correctness of which I confirmed in the same sample), it follows that 43.979 grms. of absolute phenic acid entered into union; leaving 6.011 grms., or 12 per cent of the 50 grms. weighed, to be set down as water, impurity, and unappropriated phenol.

Although phenol is not miscible in sulphuric acid before combination, or much more soluble in dilute sulphuric acid than in water, it is miscible in all proportions with concentrated sulphophenic acid, and in less than half its bulk of sulphophenic acid diluted with 4 volumes of water. The addition of much more water precipitates the phenol, which is again dissolved by the addition of a little more sulphophenic acid. Hence, uncombined phenol, however abundant, cannot be separated from sulphophenic acid by water.

The phenol which remains free is less readily removed from the product than the uncombined sulphuric acid; and if the diminution of the former could be secured by a proportionate increase of the latter, without doubt the quantity of sulphuric acid should be increased to this end. But any considerable excess of sulphuric acid prevents the crystallisation of the crude sulphophenic acid; and whether it be due to non-occurrence of crystallisation or not, so far as I have been able to ascertain by the odour and the intensity of qualitative tests, even large stoichiometric excesses of sulphuric acid still leave nearly the same quantity of phenol not appropriated.

The uncombined sulphuric acid is very perfectly and readily removed from the diluted mixture by carbonate of barium, added carefully until the filtrate is precipitated by neither solution of barium nor by sulphuric acid; and this agent will continue to be preferred for this purpose. Oxide or carbonate of lead leaves traces of lead sulphate, and carbonate of lime more than traces of lime sulphate in aqueous solution; but as the sulphophenates are better purified by crystallisation from alcoholic than from aqueous solution, and as the sulphate of lime can be filtered clean from alcohol, the very cheap carbonate of lime may be found applicable in the pharmaceutical manufacture of the salts of sulphophenic acid.

The residual phenol may be removed (1) directly from liquid crude sulphophenic acid by repeated washings with stronger ether. The washing should be continued until the ether, syphoned off, leaves a residue free from the odour of phenol, and, when warmed with nitric acid and then saturated with potassa, is not more than faintly coloured. The water taken up by the ether will carry traces of sulphophenic acid, responding slightly to the latter test. The uncombined phenol is also left behind, (2) by crystallisation of the sulphophenates, preferably from alcoholic solution. When free sulphophenic acid is to be prepared as a final product, its barium salt is decomposed by an equivalent quantity of sulphuric acid, or the calcium salt by oxalic acid or in alcoholic solution by sulphuric acid, or the lead salt by sulphydric acid.

The combination of sulphuric acid with phenol, at any temperature, develops the wine tint which is seen, to a greater or less extent, in sulphophenates; the colour being somewhat deeper if a high temperature has been employed. The application of 300° F. for one half-hour occasions a bright wine colour to be transmitted through a layer 3 inches deep; and the temperature may be kept for some minutes at the boiling-point of phenol (369° F.), with a scarcely perceptible deepening of the tint. This colour is (mainly if not wholly) due to a substance removable from liquid sulphophenic acid by ether washing. In the first washing, the supernatant ether shows a tint of the same depth as the washed acid below; but in subsequent washings the ether colours itself rather less deeply than the tint of the aqueous layer, and I am scarcely able to say that it is practicable to remove every trace of

colour by this means. The evaporation of the decanted ether leaves behind the colour substance a thick, oily liquid of intense blood-red colour, very little odour, fiery taste, strong capillary attraction, colouring paper without the production of a transparent spot, soluble in alcohol, but insoluble in water, very slight acid reaction (probably due to contamination). Heated with soda-lime, it does not generate ammonia; its colour is not changed by chloride of lime, or by heating with corrosive chloride of mercury. The colour removed by ether from carbolic acid which has grown brown in the light is an altogether different substance. I have not succeeded in removing more than traces of colour from crystallised sulphophenates by ether.

Sulphophenates are prepared (1) from crude sulphophenic acid by its direct union with bases or their carbonates; (2) in the same manner from the acid purified only by removal of sulphuric acid, or purified by removal of both sulphuric acid and phenol (ether washing); (3) from crystallised sulphophenates of barium or calcium, or lead, by double decomposition with sulphates or carbonates (calcium) of the bases desired; (4) sulphophenate of zinc by decomposition of the lead-salt with metallic zinc; (5) from sulphophenic acid, first set free from its crystallised salt, and then combined with the bases or their carbonates. By careful and repeated crystallisations, a pure product may be obtained even by the first method, but it is certainly preferable to remove the free sulphuric acid as in the second. For administration, the close removal of the phenol is imperative, as sulphocarbolates are given in doses relatively large.

Sulphophenic acid is soluble in alcohol, insoluble in ether and chloroform. Its salts are sparingly soluble in cold, freely soluble in hot alcohol, insoluble in ether. Pure sulphophenic acid, in aqueous solution of 2 to 5 per cent, promptly coagulates albumen, as likewise do the sulphophenates with acetic acid; but the neutral sulphophenates of alkalies and alkaline earths do not coagulate albumen. To ascertain antiseptic powers, a comparative trial was made by immersing and setting aside pieces of fresh lean meat in the following liquids:—

- (a). Distilled water.
- (b). One per cent solution of sulphophenate of sodium.
- (c). Five per cent "
- (d). Five per cent solution of purified sulphophenic acid.
- (e). One per cent solution of sulphuric acid.
- (f). One per cent solution of phenol.

At the expiration of 24 hours, a slight odour of incipient animal decomposition was observable from (a), (b), and (c).

At the end of 36 hours, (b), (c), and (a) evolved offensive odours, that of (b) being decidedly most offensive, while (a) was somewhat less offensive than (c). At this time some sulphate occurred in (c), as evinced by barium precipitate, none being found in (a). Solution (b) was now thrown out.

After 46 hours the putrefaction in (c) had advanced little farther than at the previous observation, and was less offensive than that of (a), while the filtrate of (c) gave a heavier precipitate of barium sulphate than before. A very slight barium precipitate was now obtained from (d).

After 60 hours the putrefaction in (c) had extended but slightly beyond that previously noted, while the solution gave a still somewhat increased barium precipitate. The barium precipitate from (d) was still very slight. Not the slightest factor was discoverable in (d), (e), or (f) (I need hardly state) in (f). A 5 per cent solution of sulphophenic acid which had stood open during this time, in the same room, gave no precipitate with chloride of barium. No odour of phenol was detected in (c).

It would seem from these observations that sulphophenic acid has a coagulating power and antiseptic effect sufficient, in tolerably concentrated solutions, to preserve animal substance, and that the contact of the coagulated substance effects a very slight separation of sulphuric acid. Also, that sulphophenates do not at all delay the inception of animal decomposition, but do, in some degree,

retard the progress of such decomposition, in consequence of which the sulphophenate suffers decomposition (into sulphate, sulphuric acid, and phenol), while no perceptible odour of phenol is evolved.

Neither sulphophenic acid nor its salts suffer decomposition in aqueous solution in the air, and neither suffer more than slight decompositions by long boiling in dilute solutions.

The most delicate test for sulphophenic acid is that likewise the most delicate for phenol,—the production of picric acid and its salts. Strong nitric acid is added and heat applied to form tri-nitrophenic acid instead of the mono- or di-nitrophenic acid, liable to remain if heat be not used. According to Carey Lea, water containing 100000 of tri-nitrophenic acid is distinctly yellow, and when only 100000, the tint is perceptible in a stratum 1 inch deep. The delicacy of the test is much increased by adding sufficient potassa to neutralise both the picric and undecomposed nitric acids. I find that 1 part of sulphophenate in 50,000 parts of water, boiled with nitric acid and saturated with potassa, appears distinctly yellow in a stratum 1 inch deep, and that 1 part of phenol in 100,000 parts of water, treated in the same manner, produces an equal depth of tint. The tri-nitrophenate of potassa, requiring 260 parts of cold water for solution, is easily crystallised in its beautiful slender yellow needles.

The composition of sulphophenic acid authorises its classification with the sulphovinic acids, and the brotherhood of their derivatives indicates close relationship between phenol and the alcohols. The exceeding interest of these chemical analogies is enhanced by the fact that both sulphophenates and sulphethylates are at the present time on trial as therapeutic agents, and that both are believed to suffer similar and gradual decompositions in the animal body—the former furnishing phenol as a medicinal agent, and the latter yielding sulphate as the active agent. Phenol has the composition of a monatomic alcohol; it is neutral to test-papers, and its combinations with bases are scarcely stable enough to be classed as salts.

Sulphethylic acid is much less stable than sulphophenic acid; the former in dilute solutions decomposes gradually in the air and more rapidly on boiling, while the latter may be concentrated on the water-bath or even boiled without injury. The former decomposes at its own boiling-point, evolving oxide of ethyl; the latter decomposes at the boiling-point of phenyl hydrate, which distils, for some time, intact. An attempt to produce phenic ether by distillation from sulphophenic acid serves to show that, if possible, it must succeed by the introduction of peculiar conditions. When the boiling-point rises above that of phenol, that substance has mostly passed over, and sulphurous acid and quite indeterminate oxidised products appear. The double oxides of phenyl and methyl, phenyl and ethyl, phenyl and amyl, &c., are well known, but may perhaps as well be considered phenates as conjugated ethers, certainly simple phenic ether has not been obtained from them. Scrugam inferred the production of oxide of phenol in the reaction between chloride of phenyl and phenate of sodium, heated, but distillation failed to furnish the supposed product. Finally, Hoffmeister (*Deut. Chem. Ges. Ber.*, iii., 747, and *Ann. Chem. Soc.*, April, 1871) has declared the production of oxide of phenyl by distilling phenol with sulphate of azophenylamine.*

The purified phenic ether is a colourless solid, melting at 82° F., and boiling at 478° F. (or 190° above the boiling-point of phenol). The difficulty of phenic etherification seems to be explained in the fact that the ether has a higher boiling point than its alcohol. The new product is described as very stable, having an agreeable aromatic odour, and its therapeutical properties will be looked for with interest.

Should it be found that sulphophenates are producible with other than the typical formula, $\text{MO} \cdot \text{C}_{12}\text{H}_5\text{O} \cdot 2\text{SO}_3$ (or

* $\text{HC}_6\text{H}_5\text{N}_2\text{SO}_4 + \text{HC}_6\text{H}_5\text{O} = (\text{C}_6\text{H}_5)_2\text{O} + \text{H}_2\text{SO}_4 + \text{N}_2$.

$\text{MC}_6\text{H}_5\text{SO}_4$, the fact will scarcely present a dissimilitude with the sulphethylates. For we have ethionic acid, $\text{C}_4\text{H}_6\text{O}_4\cdot 2\text{SO}_3$ (in the salts of which two molecules of base are substituted for two of water), and isomers of sulphethylic acid are described.

An analysis of selected crystals of sulphophenate of barium, dried in fine powder at 212°F ., until it ceased to lose weight, gave the following results for 1000 grms. :—

	Found.	Calculated from $\text{BaO}\cdot\text{C}_{12}\text{H}_{10}\text{O}_2\cdot 2\text{SO}_3$.
BaO	0.3165	0.3167
SO_3	0.3224	0.3312

The baryta was precipitated with dilute sulphuric acid. For the determination of the sulphuric anhydride, the salt was decomposed with strong nitric acid on the water-bath, in the presence of an excess of nitrate of barium; most of the nitric acid evaporated, and the remainder nearly neutralised with potassa, and the precipitate washed first by decantation and then on a filter in the usual manner. It is difficult to decompose by nitric acid without loss of sulphuric acid, unless in the presence of excess of barium salt.

It is stated (*Rabantan, Schmidt's Jahrbucher*, 148, 610) that sulphethylate of sodium, when administered, very gradually splits into sulphate of sodium and alcohol in the alimentary canal, and the dose of the sulphethylate may be 380 grains—not higher than the dose of sulphate.

Dr. Sansom (*Practitioner*, 1869, July) states that after the administration of sulphophenates, an increased quantity of sulphates appears in the urine, while the breath bears the odour of phenol. He gives doses as large as 1 dram, which, if fully decomposed in the body, would yield over 20 grains of phenol, or many times the dose of this agent. Thus the therapeutical potency of these agents shows that sulphophenates are less easily decomposed than sulphethylates, in the animal body as well as in the laboratory.

MINERALOGY.

THE second lecture of the course, by W. W. Smyth, F.R.S., was on "Calcareous or Lime-Containing Minerals."

In the minerals included under this term, lime (Latin, *calx*) forms the principal constituent. The first of the series is that known as "calcite," which the lecturer characterised as one of the most protean substances in Nature. Its percentage chemical composition is— CaO , 44; CO_2 , 56. In its purest state it is frequently found as crystals, associated with the ore of lead, or lining the joints and fissures which are so common in limestone rocks: in the latter case it is sometimes in crystals, sometimes in the form of layers on the sides of the fissura. A variety of calcite known as "dog-tooth spar" is of frequent occurrence in the central parts of England. Calcite crystallises in the hexagonal system, and possesses some wonderful and interesting physical properties. One of the most remarkable is that of double refraction, which is seen to great advantage in crystals of Iceland spar, although not peculiar to that substance. It consists in the splitting up of an incident ray of light into two portions, which in their passage through the crystal are more or less separated from each other, the distance of separation increasing with the thickness of the crystal. Two fine specimens were exhibited; one in its native state, with a smoky film on its surface; the other, which had had this film cleaved off, was beautifully transparent, and on looking at a wafer placed beneath two distinct figures of it might be seen. Another property which calcite possesses, in common with some other minerals, is that of cleavage, by which all the pieces of a broken crystal will take the same form as the perfect crystal, or at least have the same angular measurements.

Another group in the series is that of the marbles, which

was known to the ancients, and applied by them to ornamental purposes. They gave the name "marble" (from a Greek word, meaning "to shine") to any substance which would take a polish and was capable of being applied to decorative purposes. We restrict the term to carbonates of lime, of a certain degree of hardness, and susceptible of a certain amount of polish. One of the purest varieties of marble, and one which was highly valued in olden times for sculptural purposes, is that known as "Parian marble," which is obtained from the Island of Paros, in the Grecian Archipelago. Another variety, which is far more common amongst us now, is the Carrara marble, which, under the name of Marmor Lunensis, was in great repute in the time of the Roman Empire. The modern town of Carrara stands on the shores of the Gulf of Genoa, and the entire population of the place is supported by the produce of its marble quarries. There are other varieties of Carrara marble besides the pure white statuary rock, marked in various ways; and in fact there are frequently, in all limestone districts, numerous varieties which are quite peculiar to that district. Thus we have black marble from Kilkenny, in Ireland, and extremely varied kinds from Derbyshire and Yorkshire. But as a rule the limestones of this country, in point of beautiful colours, are inferior to those of the South of Europe, the only notable exception being a variety, Devonian marble, from near Torquay.

The Lecturer also remarked, as a curious fact, that as you proceed southward in Europe you find a more and more extensive use of these beautiful stones, and of other natural productions, in domestic architecture, and expressed a desire to see this practice more common in this country. But the wealth of this country in these kinds of rocks consists in the vast beds of "limestone," generally so-called, which are carbonates of lime more or less incapable of taking a fine polish. These stores of limestone have not yet been developed to their full extent, and, speaking generally, the mineral resources of our island have not been properly investigated; in many cases we have had to depend for supplies on foreign sources. The chief object of this Museum of Practical Geology is to illustrate and teach what is known and what is being discovered on this subject.

This same substance is also found in the form of stalactites and stalagmites, so frequently to be seen in the caverns of limestone districts. The name "stalactites" is given to those masses which hang pendant from the roof, "stalagmites" to those which rise from the floor. Their principle of formation is due to the fact that water, holding carbonic acid in solution, is capable of dissolving and carrying away portions of limestone, leaving, in most cases, hollows or caverns in the rocks; and this explains the prevalence of caverns in limestone districts. The carbonic acid is derived by rain water, partly from the air and partly from decomposing vegetable and animal matters. When the water evaporates the lime is left behind,—as, for instance, in the case of the drops in the roof of the cavern,—and a stalactite is formed, and grows by the addition of matter from the water trickling down outside it, though sometimes there is a narrow pipe down the centre of the mass. A section across one of these is often curiously variegated, both in the colour and form of the various layers, and in this way (more especially by sections of the stalagmites) the ancients obtained what they termed "alabaster," or what is now known as "Algerian onyx."

The hydrated sulphate of lime, or gypsum, is quite distinct from the above carbonates; it crystallises in the oblique system. Fine crystals of it are found in the counties of Nottingham and Derbyshire, where it is manufactured into plaster of Paris by merely driving off its water. Its composition per cent is— CaO , 32.6; SO_4 , 46.5; H_2O , 20.9.

A phosphate of lime is also known, under the name "apatite," in which 89 to 92 per cent of calcic phosphate is combined with fluoride or chloride of calcium. Great

quantities of this phosphate of lime have been imported for use as artificial manure.

Fluor-spar is another calcareous mineral found crystallised in cubes, of various colours, the purples and blues predominating. It is known in Derbyshire as "blue John," and is capable of being worked into most beautiful objects. Its percentage composition is—Ca, 51·9; F, 48·1.

FLUORESCENT RELATIONS OF CERTAIN SOLID HYDROCARBONS FOUND IN PETROLEUM DISTILLATES.

By HENRY MORTON, Ph.D., President of the Stevens
Institute of Technology.

WHEN the residues left in the distillation of petroleum for the manufacture of illuminating oils are re-distilled to obtain lubricating oils and paraffin, there passes over near the close of the operation, and when the still is at the bottom almost or even quite red-hot, a thick tarry matter of a sepia colour, which is used like the corresponding product of coal-tar distillation as a lubricant for very heavy and rough machinery, such as the necks of the rollers in iron rolling-mills.

A specimen of this was given to me in the early part of last February by Prof. E. H. Horsford, and on examination and treatment with benzene, alcohol, and ether, I extracted from it a solid crystalline body of a yellow-green colour, and remarkable fluorescence. This I described under the name "viridin" in a paper read before the American Institute in New York, on the 29th of March, and drew attention to the very remarkable spectrum which its fluorescent light yielded, which resembled in a remark-

FIG. 1.

In this woodcut the centre of first shade should be at 6, and not at 6·2, as it is.

FIG. 3.

able manner that of anthracene, while the crystalline form, solubilities, and fusing-points of the two bodies were decidedly unlike.

The amount of material given me by Prof. Horsford was, however, insufficient for further study, and I encountered some difficulty in obtaining a fresh supply. At last through the kindness of my friend, Dr. G. F. Barker, with whom I am now engaged in a thorough investigation of the properties of this material, I was introduced to Mr. John Truax, who has kindly supplied me with an abundance of the required material with which the observations about to be described were made.

To make clear what follows, I must say a few words about the preparation of the substance, although for all details I would refer to the paper by Dr. Barker and myself, to appear subsequently.

The crude tarry matter is well washed with benzene (petroleum naphtha), then with alcohol, and is lastly dissolved in benzene (coal-tar naphtha), filtered hot, and

crystallised out on cooling. It is then obtained as a mass of very minute needle-like crystals, of a greenish-yellow colour and pearly lustre in the mass. If a portion of this is illuminated with light which has passed through a tank of ammonio-sulphate of copper, it is seen to emit a brilliant green light, and if this is examined with a spectro-scope the spectrum shown in Fig. 1* is seen.

The method actually employed for these observations is represented in Fig. 2 where A represents a port-lumière with a lens of about 12 inch focus at B, a tank of ammonio-cupric sulphate in front of that, and in the focus of the lens a little bottle containing the substance supported in a rotating stand, C, so arranged with a "click" that one bottle after another could be brought rapidly into an identical position.

A Browning's one-prism spectroscope was then employed at D to examine the fluorescent light.

If now we fuse a portion of this substance with paraffin and allow it to cool in a thick layer on glass, and examine the light which it will transmit, we shall find that it yields an absorption-spectrum such as is shown in Fig. 3. First comes a relatively narrow and sharply defined band about F, then a very broad and less sharply defined line which contains two maxima of absorption, one about 10·1, and the other about 10·9, of the scale. Lastly, we have a yet more indefinite band about 12·5 reaching to G, and connected by a shade of slight general absorption with the point about 14 of the scale, above which the absorption is total.

The detail of the method of observation here employed is illustrated in Fig. 4, where A is the port-lumière, B a lens of 12-inch focus, C a tank of ammonio-cupric sulphate, D the object to be examined, and E the spectroscope.

These absorption-bands are not only to be seen in the mixture of the above-described body, which I may as well

FIG. 2.

call thallene hereafter to avoid circumlocution, with paraffin, but also in the thallene alone when fused into a thin film by heating between two pieces of mica, and even in paper coated with a mixture of thallene and demar varnish.

If now a pure spectrum of sunlight is thrown on a screen of paper coated with the mixture of thallene and varnish last mentioned, it will be observed that a strong fluorescence is excited by all the rays above 8·5 of the scale, but having decided maxima corresponding with the absorption-bands shown in Fig. 3, and a very intense fluorescence of a rich green colour beginning about 14 where the absorption is total. Below this point the fluorescent light combined with that of the spectrum gives a white ground on which the Fraunhofer lines show with remarkable distinctness. The two H lines come out beautifully on the bright green above 14, and with prisms

* The scale used for all these drawings of spectra is that introduced by Bunsen, with millimetre divisions.

and lenses of quartz the spectrum lines can be seen to a great distance above always on a bright green ground.

As a screen on which to project and study the lines of the extra violet spectrum, either of sunlight or of various elements as described by Stokes,* this substance applied as above seems to exceed very decidedly in brilliancy of effect the peculiar uranium phosphate used by that investigator.

In fact, if, with a brush filled with what we might call this thallene varnish, we write or paint words, or leaves of flowers and the like on a card, and then view it by light which has passed through cobalt glass, the writing or figures seems to be self luminous, so bright is its fluorescence, exceeding even that of the platino-cyanide of barium, which was heretofore the most brilliant solid in this respect. I have just prepared in this way, for a lecture illustration, a flower some 10 feet across, using the above material to paint the leaves and buds, and another to be presently described for the petals, and find that with a lime-light lantern and cobalt glass it lights up in a very surprising manner. With an electric light of course the effect is still better.

In a lecture which I delivered last week (Nov. 6) in the Opera-house in Philadelphia, which seats 3500 auditors, I used a screen 8 feet long by 2 feet wide coated with this substance, and placing it beyond the violet end of a

FIG. 4.

spectrum thrown from an electric light with 60 Bunsen's cells and two bisulphide of carbon prisms, I found that many of the lines of copper, silver, magnesium, and other metals which were invisible on a screen of paper, come out so strongly that they were plainly viewed by every individual in the audience which filled the building on that occasion.

FIG. 5.

FIG. 6.

Thallene in Solution.—If this substance is dissolved in benzol which will take up at the ordinary temperature about 1 part to 150, a rich yellow liquid is obtained fluorescing with a blue colour and considerable intensity; and when this light is examined with the spectroscope it is found to resolve itself into a spectrum which is indicated below in Fig. 5. Comparing this with Fig. 1, and bearing in mind the correction required in the first band of that figure, it will be seen that in the spectrum of the fluorescent light given by the solution, all the bands are moved towards the more refrangible end of the spectrum.

* *Phil. Trans.*, 1862, II., p. 602.

Thus in the spectrum of the solid we have the centres of the principal bright bands at 6·8 and 8·4, and in that of the liquid at 7·2 and 8·9. In addition to this we perceive that a new bright band has made its appearance at 10·7. On careful examination of the solid, however, in a very strong light, and with a plate of violet glass added to the ammonio-cupric sulphate tank at c (Fig. 4), it appears that a corresponding band exists at about 9·8, though it is very faint. If now we change the solvent to chloroform, in which the thallene dissolves to about the same extent as in benzole, we find the displacement of bands still the same, or not appreciably different.

If, however, we use ether, which dissolves but a small amount, we find the bands displaced yet further up; the principal bright bands, which in the solid are at 6·8 and 8·4, in the benzol solution at 7·2 and 8·9, are in the ethereal solution at 7·4 and 9·2. The spectrum of the solution in alcohol, which dissolves but about 1 part to 12,000, is very much like that of the ethereal solution, as is also the spectrum given similarly with solution in turpentine; that in olive oil is between the solutions in benzole and ether in the upper displacement of its bands.

On the other hand, a solution in carbon-bisulphide shows a displacement of the bands only about half as great as that observed with the solution in benzole.

In all cases of solution we find an elevation of the bright bands in the spectrum; and it is without doubt to this, mainly, that is due the general change in the colour of the fluorescent light, from green in the solid, to blue in all of the solutions.

If now we observe the solutions in the manner indicated in Fig. 4 (and for this purpose I find it very convenient to place them in bottles of white glass of one ounce capacity, these bottles forming cylindrical lenses of a convenient focal length to throw a large amount of light into the slit of the spectroscope), we shall find that the absorption-bands, like those of fluorescence, are displaced upwards, and to a similar degree, without, as a rule, any other change.

This is shown in Fig. 6, which represents the absorption-spectrum of the solution of thallene in benzole.

In the case of the solutions in carbon-bisulphide and in turpentine, it should be observed that the band nearest to F is entirely, or almost entirely, wanting, while the other two are well defined and very strong.

When a glass tank is filled with one of these solutions, and a pure spectrum is projected upon its vertical side, distinct maxima of fluorescence are observed in places corresponding with the absorption-bands, exactly as was the case when the solid thallene was used similarly as a screen, the maxima now, of course, coinciding with the displaced absorption-bands of the solution.

On looking down into the tank, long trails of fluorescent light are seen running into the solution at each maximum, these varying in tint from green in the band near to F, blue in the next, then blue-green, and in the uppermost a purplish blue.

All the actions which have been heretofore described with this body find a parallel in impure anthracene (*i.e.*, chrysogen), except that the absorption-band near F is not lost or diminished by solution in carbon-bisulphide or turpentine, and that it shows no band of fluorescence corresponding with the uppermost one of thallene.

Quite early in my observations on thallene I had noticed that its solutions, as also those of anthracene, when exposed for a short time to sunlight, ceased to give any bands of absorption, and as soon as I had established with anthracene that this was connected with the destruction and removal of a companion body (chrysogen), I tried the effect of a similar treatment upon a benzole solution of

thallene. If a solution of this body in benzole is exposed, cold, to bright sunlight for five minutes, the band near F disappears, but it requires an exposure of at least half an hour to remove the other bands. Using a hot solution, and crystallising out the material on cooling, I found that more than two hours were needed to produce thoroughly a change presently to be described, and a much longer time with a cold solution; I therefore had recourse to a large burning-glass of about 16" diameter and 3 feet focus, which was in our cabinet, and found that an exposure of ten minutes near its focus was enough to modify a 4-oz. flask, full of hot saturated solution. After such treatment the solution shows no absorption-bands, and only a total absorption above 14.5; and when, on cooling, crystals are separated, they are seen to have lost their yellow colour and green fluorescence, and are of a slightly leaden tint, and fluoresce bright blue. The spectrum of this fluorescent light shows an upward displacement of the bands a little greater than that given by the solution in ether.

To indicate the body in this condition, I would propose the name "petrollucene."

When a solution of this substance in benzole is examined, by allowing a pure spectrum to fall upon it, the maximum corresponding to the lower absorption-band is found to be entirely wanting; but the two upper maxima, one a little below G, and the other half-way between G and H, are still strongly shown, and have long trails of light running from them far into the solution.

Beside certain additions, which it will be observed that I have made to the actions of chrysogen given in a previous paper (see *CHEMICAL NEWS*, vol. xxvi., p. 199), two errors should be corrected. On page 201, first column, fourth line from foot, "green" should be "blue;" and on the second column of the same page, near the end of the fourth paragraph, "700° F." should be "460° F."

ADULTERATION OF CHEMICALS.

ACETIC acid is frequently weakened with water, and adulterated with sulphuric ether. Six samples tested with chloride of barium gave a precipitate of sulphate of barium in varying proportions.

Muriatic acid and sulphuric acid, sold as chemically pure, have both been found contaminated; the former with arsenious and sulphurous acids, the latter with a large proportion of sulphate of lead.

Tartaric acid has been met with containing 50 per cent of sulphate of magnesia. Alum is also said to be used as an adulterant, but the reporter had not met with a specimen.

Alum frequently contains iron, probably arising from carelessness in the manufacture. The presence of free acid has also been noticed, especially in the English article.

Carbonate of ammonia is sometimes substituted by a compound made from solution of ammonia, glue, and bicarbonate of soda, which forms when dry a hard translucent mass, resembling genuine carbonate.

Muriate of ammonia is sometimes met with of very poor quality; iron is often visible on the surface and becomes still more so when dissolved. The report recommends that the purified granular salt should be the only one sold at the dispensing counter.

Black sulphuret of antimony has been met with containing sulphate of lead (galena), quartz (30 to 40 per cent), clay, &c. A good article, however, is procurable.

Powdered arsenic is sometimes adulterated with sulphate of lime or sulphate of baryta; the pharmacist is, therefore, recommended to purchase the lump arsenious acid.

Bismuth (metal) generally contains arsenic. An instance is mentioned in the report where 400 lbs. of antimony were sold by a broker to a manufacturer for bismuth. Fortunately for the latter, he detected the error before the transaction was completed.

Subnitrate of bismuth has been reported as adulterated with 20 per cent of phosphate of lime; but it is believed that the salt made in the United States by the principal manufacturers is free from adulteration.

Citrate of iron and quinine is seldom found made strictly according to the United States formula, which does not produce a sufficiently soluble salt. Some manufacturers, therefore, add citrate of ammonia to make it soluble, and others leave out a considerable portion of the quinine to accomplish the same end. There is also a probability that in some cases cinchonine is substituted for the quinine.

Chloral hydrate has been met with containing the alcoholate. The tests pointed out are the difference in boiling-point, sulphuric acid, which leaves pure hydrate colourless, but turns alcoholate brown, and nitric acid, which gives little or no reaction with hydrate, but reacts violently with alcoholate, giving off nitrous oxide gas.

Chloride of calcium has been noticed at Chicago with a large excess of caustic lime, and it is known to have been sold in crystals without any allowance made.

Chloroform is sometimes met with diluted with alcohol, and sometimes not sufficiently purified, and, therefore, unfit for inhalation. There is also reason to believe that partially decomposed chloroform has been sold through ignorance on the part of the dispenser. Nitrate of silver is useful in detecting this decomposition, by giving a precipitate of chloride of silver with the liberated chlorine.

Cream of tartar is grossly adulterated, and the distinctive terms are said to be well known to mean varying proportions of *terra alba* and cream of tartar.

Epsom salt has been substituted in the Western market by finely crystallised Glauber's salt. As the prices, however, are now about the same, this is not likely to recur.

Ether is sometimes sold containing a large proportion of alcohol. This may probably arise from the druggist dispensing photographic concentrated ether, made to contain alcohol in order to dissolve the gun-cotton.

Iodoform has been noticed of a light canary colour, a considerable portion being insoluble in ether; probably iodate of lime.

Acetate of lead has been in the market containing a large percentage of crystallised nitrate of lead; one lot was offered, to a maker of preparations for the hair, as "damaged," which proved to be damaged sulphate of zinc, in lumps.

Precipitated carbonate of lime has been offered containing sufficient iron to give it a light fawn colour; supposed to be ordinary chalk, dressed.

Sulphate of morphia is frequently open to suspicion. In one case the sample did not contain any morphia; placed on a red-hot plate, it did not seem to lose any weight, and it was insoluble in water. A fraud in which sulphate of quinine was put into sulphate of morphia bottles has been lately detected in New York.

Phosphorus, according to Dr. Rademaker, sometimes contains arsenic.

Bromide of potassium has been observed to contain a considerable quantity of water of hydration.

Iodide of potassium is often adulterated with the bromide; some made in New York was found to contain carbonates in considerable quantity.

Sulphate of quinine has many adulterants; among them sulphate of lime; cinchonine, sold as "sweet quinine" or as "cinchoquinine;" muriate of cinchonine, sold as "light sulphate of quinine" and as "French quinine," salicine, &c.

Rochelle salt has been offered for salt containing at least 25 per cent of sulphate of soda.

Santonine was seen last year, in the New York market, contaminated with small particles of mica. This fraud may easily be detected by placing the suspected sample on a hot plate; the santonine will disappear and leave the mica.

Nitrate of silver (made for the Government), which contained 5 per cent of copper, was sold in Chicago.

Pieces could be picked out emerald-green in colour; it appeared to have been made by simply dissolving coin or other alloy of silver in nitric acid, and crystallising without any attempt at purification.

Precipitated sulphur is reported as usually free from sulphate of lime, and the United States pharmacist is congratulated on this superiority to the English article; but a proportion of 50 per cent of gypsum in flowers of sulphur is reported as having been noticed, and sometimes ground sulphur is sold for the sublimed.

Tartar emetic has been met with containing 11 per cent of cream of tartar.

Spices, on account of their widely extended use, are largely adulterated, and some startling revelations might be made if a spice miller could be persuaded to disgorge his ill-gotten knowledge. The only safe way to get pure powdered drugs is to pay a good price, and buy from conscientious persons who are above suspicion.

Cochineal is adulterated with sulphate of barytes, a heavy white powder, which, when shaken with the insects, lodges in the wrinkles and crevices on the surface of the body. The weight is thus increased sometimes from 15 to 25 per cent.

Balsam of copaiba is often mixed, and sometimes found entirely fictitious, being composed of a mixture of castor-oil, resin, and oil of copaiba. Powdered ipecacuanha is sometimes so adulterated and weakened that tartar emetic is necessary to strengthen it. Oil of lemon mixed with 30 per cent of fixed oil has been met with.

Powdered opium is often mixed with powdered extract of liquorice. In fact, some dealers uniformly send to the grinders a certain proportion of liquorice with the opium, so that they might be ground together. Powdered rhubarb is frequently adulterated with curcuma. Sometimes senega root is mixed with cypripedium.

Castile soap frequently contains an undue proportion of water. It has been met with containing as much as 30 per cent. Acetic acid is also mixed with water, acidulated with dilute sulphuric acid.

Subnitrate of bismuth has been found mixed with phosphate of lime to the extent of 20 per cent; and citrate of iron and quinine is adulterated with citrate of ammonia, and contains less quinine than called for, 10 or 15 per cent instead of 25 per cent. Quinine itself is frequently met with mixed with cinchona, muriate of cinchona, and salicine.

Santonine has been found adulterated with small particles of mica, and cream of tartar frequently mixed with tartar emetic. Cream of tartar is grossly adulterated; the terms "strictly pure, pure, No. 1 and No. 2," being used to indicate varying proportions of cream of tartar and *terra alba*, the latter material being largely imported from Europe for the express purpose of adulterating, the importations amounting to many tons annually.

Chloroform is sometimes diluted with alcohol, and iodide of potash in crystals mixed with bromide, and occasionally with bicarbonate of potash. Solid extracts are also much adulterated.

In the manufacture of syrup, a considerable portion of the sugar is replaced by glucose, especially in making fruit syrups.—*Proceedings of the American Pharmaceutical Association.*

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, December 2, 1872.

SIR HENRY HOLLAND, Bart., M.D., D.C.L., F.R.S.,
President, in the Chair.

THOMAS Thompson, jun., Esq., and Sidney Waters, Esq., were elected as Members of the Royal Institution. The

following lecture arrangements for the ensuing season were announced:—

Christmas Lectures (adapted to a Juvenile Auditory).

Professor Odling, M.A., F.R.S. Six lectures "On Air and Gas," on Dec. 28 (Saturday), Dec. 31, 1872; Jan. 2, 4, 7, 9, 1873. Before Easter, 1873.—Professor Rutherford, M.D., F.R.S.E. Twelve lectures "On the Forces and Motions of the Body," on Tuesdays, Jan. 14 to April 1. Dr. Debus, F.R.S. Three lectures "On Oxidation," on Thursdays, Jan. 16, 23, 30. Dr. H. E. Armstrong, F.C.S. Four lectures "On the Artificial Formation of Organic Substances," on Thursdays, Feb. 6 to Feb. 27. A. Vernon Harcourt, Esq., M.A., F.R.S. Five lectures "On the Chemistry of Coal and its Products," on Thursdays, March 6 to April 3. Edward A. Freeman, Esq., D.C.L. Six lectures "On the Comparative Political Institutions of Different Nations," on Saturdays, Jan. 18 to Feb. 22. Professor W. K. Clifford, M.A. Three lectures "On the Philosophy of the Pure Sciences," on Saturdays, March 1, 8, 15. Professor Max Müller, LL.D. Three lectures "On Darwin's Philosophy of Language," on Saturdays, March 22, 29, and April 5. After Easter.—John Morley, Esq. Three lectures "On the Limits of the Historic Method," on Tuesdays, April 22 to May 6. J. H. Parker, Esq., C.B. Four lectures "On the Evidence for the Traditional History of Rome from Existing Architectural Remains," on Tuesdays, May 13, 20, 27, and June 3. Professor Tyndall, LL.D., F.R.S. Six lectures, on Thursdays, April 24 to June 5. Professor Odling, M.A., F.R.S. Four lectures, on Saturdays, April 26 to May 17. Edward Dannreuther, Esq. Three lectures "On the Development of Music in Connection with the Drama," on Saturdays, May 24, 31, and June 7.

The Friday Evening Meetings will commence on January 17.

Friday Evening Discourses during the Season will probably be given by Wm. Spottiswoode, Esq., the Rev. Professor T. R. Birks, Edward Dannreuther, Esq., R. H. Scott, Esq., Robert Sabine, Esq., Sir H. Rawlinson, K.C.B., Professor Clerk Maxwell, James Dewar, Esq., E. J. Reed, Esq., C.B., J. Emerson Reynolds, Esq., Professor W. K. Clifford, Professor Tyndall, Lord Lindsay, Professor Odling, and others.

The presents received since the last Meeting were laid on the table, and the thanks of the Members returned for the same.

MISCELLANEOUS.

The Royal Society.—At the annual meeting of the Royal Society, held at Burlington House on November 30, the following gentlemen were appointed officers and council for the ensuing year:—*President*—Sir George Biddell Airy, K.C.B., M.A., D.C.L., LL.D., Astronomer Royal. *Treasurer*—William Spottiswoode, M.A. *Secretaries*—Professor George Gabriel Stokes, M.A., D.C.L., LL.D.; Professor Thomas Henry Huxley, LL.D. *Foreign Secretary*—Professor William Hallowes Miller, M.A., LL.D. *Other Members of the Council*—George James Allman, M.D.; Sir B. C. Brodie, Bart., M.A., D.C.L.; George Busk, F.R.C.S.; Professor Robert Bellamy Clifton, M.A.; James Fergusson, D.C.L.; Thomas Archer Hirst, Ph.D.; J. Dalton Hooker, C.B., D.C.L., LL.D.; Joseph Prestwich, V.P.G.S.; Rear-Admiral G. H. Richards, C.B.; Professor H. Enfield Roscoe, B.A., Ph.D.; Philip Lutley Sclater, M.A.; William Sharpey, M.D., LL.D.; Francis Sisson, M.D.; Major-Gen. R. Strachey, R.E., C.S.I.; Isaac Todhunter, M.A.; Sir Charles Wheatstone, D.C.L.

Royal Institution.—The two Actonian Prizes of £100 have been awarded by the Managers of the Royal Institution to the Rev. George Henslow and to Mr. B. Thomson Lowne, for Essays "On the Theory of the Evolution of Living Things."

CHEMICAL NOTICES FROM FOREIGN
SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, November 25, 1872.

This number is entirely devoted to the general annual meeting of the Academy, at which the prizes are distributed, and reports read concerning them.

Les Mondes, November 28, 1872.

Annual Public Meeting of the Academy of Sciences; Distribution of the Prizes for 1870 and 1871.—From the contents of this paper we abstract the following particulars:—The Lalande prize for astronomy has been given to Mr. Huggins, as an acknowledgment of his researches on the physical constitution of the stars, planets, comets, and nebulae. The Jecker prize (chemistry) has been given to MM. De Clermont, Gal, and Grimaux; to each of these has been given the sum of 7000 francs (£280), as an acknowledgment for their chemical researches. The Barbier prize has been given to M. Personne for his researches on choral. The prizes for 1871 relating to chemistry and collateral sciences have been distributed as follows:—The Jecker prize to Dr. Schützenberger, as an acknowledgment for his labours in organic chemistry. The Barbier prize to Dr. Duquesnel, for a memoir on crystallised acetonine. The Montyon prize and 2500 francs (£100) to M. Goldenberg, for sanitary improvements made in his manufactory. 2000 francs to M. Louvel for his process of preserving grain in vacuum.

Obituary.—Professor Klebsch, of Göttingen, one of the most eminent mathematicians of the day, has just died at the early age of forty; the deceased was also well known for his studies in astronomy and physics.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 17, 1872.

This number opens with an address of Dr. Liebreich, congratulating the President (Dr. A. W. Hofmann) and the members of the Society on the fifth anniversary of the foundation of this society, already one of the most successful scientific societies established in Germany; the speaker gives a review of the history of the past lustrum, and pays a well-deserved tribute to Dr. A. W. Hofmann, to whose energy the success of the society is in a great measure due. Dr. Oppenheim proposed that a subscription list should be opened for the benefit of the orphans of the late J. C. Brough; the amount subscribed up to November 18, was 158 thalers = £23 14s.

The following original papers and memoirs are contained in this number:—

Researches on the Uric Acid Group.—M. Nencki.—After referring to his former researches on this subject, the author states that, when barbituric acid is treated with cyanogen gas, there is formed cyan-malonyl-urea, $C_4H_4N_4O_4$; the formation of this body from barbituric acid is simply due to the addition thereto of cyanogen, and takes place according to the following formula:—

Cyan-malonyl-urea is not decomposed by boiling with water; it is a solid crystalline substance, which, when heated to 240°, gives a small sublimate, but is mainly carbonised and decomposed. Strong sulphuric acid decomposes cyan-malonyl-urea at 100°; carbonic acid is evolved, and several new products formed. By the action of caustic potassa solution, a new acid is formed, which the author terms cyan-uronic acid; the potassa salt of this acid has the formula $C_6H_4KN_6O_4$. The free acid is a solid substance, difficultly soluble in water, but this substance is an unstable compound, because it is slowly decomposed by contact of air, hydrocyanic acid being given off; the formula of the free acid is $C_6H_4N_6O_4$. The acid alluded to is, according to the author's researches (compared with those of Bayer, *Ann. d. Chem. u. Pharm.*, vol. cxxv., p. 312), identical with malobiotic acid—

Dehydration (Wasserentziehung) as Taking Place in the Animal Organism.—M. Nencki.—Reserved for full translation; an observation also applying to the following essay:—

On Ultramarine.—C. Unger.

On Nitro-Naphthalenes.—A. de Aguiar.—This exhaustive essay treats on dinitro-naphthalin-a, which is soluble in glacial acetic acid; it is a yellow-coloured crystalline substance, and, when treated with strong nitric acid, yields some trinitro-naphthalin, but chiefly tetra-

nitro-naphthalin-a, and also nitro-phthalic acid, $C_8H_4(NO_2)_4COOH$. The crystallographical features of this body are described at length, and illustrated by woodcuts; the chemical properties agree with those described by Marignac. Nitro-phthalate of baryta is a crystalline salt barely soluble in water; it contains no water of crystallisation; formula—

Nitro-phthalate of silver is an amorphous compound, soluble in acids, and exploding when heated; formula—

A considerable portion of this essay is devoted to a comparative review of the author's and Dr. Beilstein's researches on this subject; the modes of preparation of the above compounds are also exhaustively described.

On Triphenyl-Methan.—A. Kekulé and A. Franchimont.—In the introduction to this paper the authors observe that it has become customary to view the hydrocarbons of the benzol series as derivatives from benzol, for the hydrogen atoms of which have been substituted monovalent (*cinwerthige*) alcohol radicals; instead of this view being taken, the hydrocarbons just mentioned might be referred to substances of the fatty bodies, by considering that for a certain number of hydrogen atoms of these, remnants (*reste*) of benzol have been substituted. This has already been done for the alcohols, aldehydes, and acids of the aromatic series, and when applied to the aromatic hydrocarbons starting from methan, the simplest hydrocarbon of the group of the fatty bodies, the following series will be obtained:—

The preparation of triphenyl-methan from mercurio-diphenyl is then described at length; the pure substance is a solid crystalline body, fusing at 92.5°, boiling at 355°, insoluble in water, readily soluble in ether, boiling alcohol, and boiling benzol. Triphenyl-methan forms with benzol a solid crystalline combination, which fuses at 76°, the benzol being gradually eliminated by the application of a higher temperature, so that at 92.5° there is only triphenyl-methan left; the simplest formula of this body is $C_{18}H_{12}$, while its constitutional formula is that quoted above. With fuming sulphuric acid, triphenyl-methan forms a sulpho acid; formula, $CH(C_6H_5)_3SO_3H$; the baryta salt of this acid is soluble in water, but is precipitated from this solution by alcohol.

Benzophenon Chloride, and the Formation of Anthrachinon by the Preparation of Benzophenon.—A. Kekulé and A. Franchimont.—The preparation of benzophenon chloride, a rather difficult operation, is first described at length. In pure state, the body is a colourless very refractive fluid; sp. gr. at 18° = 1.235; boiling-point, at ordinary barometric pressure, from 298° to 300°, and, with the thermometer fully in the vapour, 305°; it is slowly decomposed by cold water, rapidly so by hot. The researches on the reactions of this body are not yet finished, but the authors observe that, while preparing benzophenon, some anthrachinon was formed; the formation of this body (benzophenon being prepared by the dry distillation of benzoate of lime) is considered due, not to any impurity in the substances employed, but to a peculiar condensation of benzoic acid, elucidated by the fact that anthrachinon has the composition of a second hydrate of benzoic acid—

Chlorated Azo-Derivatives of Benzol.—K. Heumann.—The researches recorded in this memoir have been made to ascertain how far the differences existing between the two isomeric modifications of monochlor-nitro-benzol are carried over to the derivatives of these bodies; for this purpose a-chlor-nitro-benzol has been treated by the author with caustic potassa solution, the result of the operation, after purifying the substance formed, being the production of a compound, $C_{12}H_8Cl_2N_2O$, dichlor-azoxy-benzol; structural formula—

fusion-point, 155° to 156°. The β -chlor-nitro-benzol yields, although in small quantity, by the same mode of treatment, the same substance, which is readily nitrated, thereby yielding a new compound—

This dichlor-nitro-azoxy-benzol fuses at 134°, is entirely insoluble in water, and is dissolved with difficulty in alcohol; it is crystalline, and is, by the action of fuming sulphuric acid, converted into dichlor-azo-benzol, a solid substance, insoluble in water, somewhat soluble in boiling alcohol; fusion-point, 183°.

Action of Sodium upon Chlorated Nitro-Compounds.—Dr. A. W. Hofmann and A. Geyer.—This essay contains the account of a series of researches, which were not completed, and also relates to solid chlor-nitro-benzol (fusion-point, 83°), and the action of sodium upon the ethereal solution of that body. The authors obtained, in addition to dichlor-azoxy-benzol, $C_{12}H_8Cl_2N_2O$, a hydro-compound,

1873, LONDON INTERNATIONAL EXHIBITION.
SURGICAL INSTRUMENTS.

Rules and Forms of Applications may be obtained on application to the Secretary.—Offices, International Exhibition, Upper Kensington Gore, London, S.W.

BERNERS COLLEGE OF CHEMISTRY.—EXPERIMENTAL MILITARY AND NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The LABORATORY will be open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under $\frac{1}{2}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{2}$ per cent

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA OF HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 2s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG'S signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ship's Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian and other Governments.

ESTABLISHED 1798.

ROBERT DAGLISH & CO.,
BOILER MAKERS, ENGINEERS, AND
MILL-WRIGHTS,
BRASS AND IRONFOUNDERS,
ST. HELEN'S FOUNDRY, LANCASHIRE.

Makers of every description of Chemical, Colliery, Copper Ore Mining, and Glass Machinery, including Crown, German Sheet, and Plate Glass Plant, as supplied to some of the largest Firms in England, Ireland, Scotland, and Wales.

Makers of the latest Improved Revolving Black Ash Furnace, with Siemens's Patent Gas Arrangement, and as used in the Manufacture of Soda.

Air Engines for Acid Forcing Ammonia Sulphate of, Plant Agitators Cast- and Wrought-Iron Caustic Pots.

Dormoy's Patent Rabble for Black Ash Making, &c.

Decomposing Pans.

Gas Producers for Heating Pans.

Pyrites Burners for Irish, Norwegian, and Spanish Ores.

Retorts, Acid, Gas, Nitre, and Vitriol.

Steam Superheater for Resin Refining, &c.

Sulphur Pans and Stills.

THE CHEMICAL NEWS.

VOL. XXVI. No. 681.

PRELIMINARY NOTICE

ON THE IODO-DERIVATIVES OF THE ORCINS.

By JOHN STENHOUSE, LL.D., F.R.S.

IN 1864 (*Journ. Chem. Soc.*, vol. xvii., p. 327) I published an account of teriod-ormin, obtained by the action of iodine protochloride on an aqueous solution of orcin, but I found I was unable by this process to obtain any other iodo-derivative of orcin.

Monoiod-ormin, $C_7H_7IO_2$.—When an ethereal solution containing a molecule of orcin and one of iodine is agitated with dry precipitated mercuric oxide, the colour rapidly disappears and an iod-ormin is formed. On distilling off the ether, and extracting the residue with hot benzol, the iod-ormin separates in the crystalline state on cooling. In this reaction, powdered lead oxide (litharge) may be advantageously substituted for the mercuric oxide, since the lead oxide produced is not dissolved when the residue is extracted with benzol. Two or three alternate crystallisations from benzol and from water suffice to render the iodide pure; but, if mercuric oxide has been used, it is advisable to employ a dilute solution of potassium iodide for the first crystallisation, to prevent the mercuric iodide crystallising out along with the iod-ormin.

Monoiod-ormin, as thus prepared, is a colourless crystalline substance, which melts at about 86° , and decomposes, with evolution of iodine vapours, when heated more strongly. Gently heated with concentrated sulphuric acid, the substance is decomposed and iodine freely liberated. Iod-ormin is only slightly soluble in cold water, but readily in hot water. It is very soluble in ether and in hot alcohol; moderately soluble in benzol and in hot petroleum, crystallising out from the latter almost entirely on cooling; slightly soluble in carbon disulphide. It is quite destitute of the peculiar astringent sweet taste so characteristic of pure orcin.

Monoiodo-resorcin, $C_6H_5IO_2$.—This compound, prepared in a similar manner to the corresponding orcin compounds, is a colourless crystalline substance, closely resembling the iod-ormin in its general characters, but much more soluble in water.

When the monoiod-ormins, in ethereal solution, are again treated with iodine and a metallic oxide, more of the hydrogen is replaced, producing the higher iodo-compounds; these I am at present investigating, and hope, by pushing the action to the fullest extent, to obtain penta-iodo-ormins corresponding to the chlorine and bromine derivatives, of which I have already published an account.

ON THE PRESENT POSITION OF SCIENCE IN RELATION TO THE BRITISH GOVERNMENT.*

By G. GORE, F.R.S.

IT is a matter of great importance to this nation, and of special importance to the scientific men of this country, to clearly realise the position which science at present occupies in relation to our Government. That position will probably be further brought to light by the evidence which is now being given by our leading scientific men before the "Royal Commission for the Advancement of Science."

* Read before the Social Science Association, Plymouth, 1872.

For many years science has been of immense practical value to us; it has, by means of its discoveries, originated all our telegraphs, railways, steamships, gas lighting, photography, electro-plating, artillery, and nearly all our great manufactures. It has led to the expenditure of hundreds of millions of pounds upon these and other matters, and at the present time this nation largely exists upon the applied results of scientific discovery. There was a period when we did not possess such evidence of the great value of science; but that time has passed away, and our governing men have had abundant proof of the national importance of scientific discovery, and of the essential dependence of the welfare of this country upon scientific research. It is upon these grounds, therefore, that our Governments are expected to consider their duty with regard to science.

Scientific discovery and research (as distinguished from invention) is *national* work, and it is a duty of the State to provide and pay for it, because the results of it are of immense value, and indispensable to the nation; also, because nearly the whole benefit of it goes to the nation, and scarcely any to the discoverer; and because there exists no other means by which scientific investigators can be paid for their labours.

It is barely credible that, whilst the non-productive classes of the community are justly protected in the enjoyment of titles and material wealth which they have not earned, the greatest scientific workers and benefactors of the nation receive actually no payment for their labours, and the nation in general, and the non-productive classes in particular, reap the pecuniary benefit. The chief benefits of science go to the enrichment of the great manufacturers and capitalists, and finally and permanently to the great landowners, by increasing the value of land. It does not add to the dignity of one class of persons that they should be living largely upon the unpaid labours of another class; and it tends to produce evil feelings between them.

It may be objected that scientific men ought either to sell their discoveries or protect them by means of patents. Neither of these courses are possible. Scientific discoveries, although of such great value, are not saleable things; because they have not been converted by the process of invention into practical shapes, and because they cannot be protected by patent. They cannot be protected, because they are so universal in their applications. A single discovery often originates more than one hundred inventions, as may be readily seen by the number of patents taken out for the application of a single discovered substance, such as gutta-percha or india-rubber. No man could have secured to himself the discovery of the chemical action of light, because of the great number of persons who would have applied it to useful purposes, and used the applications; to claim such a discovery would be a considerable approach towards monopolising the benefit of light itself.

It is only when a discovery has been adapted to some particular use in some special way, by means of invention, that its discoverer can protect a part of it by patent, and reap any pecuniary benefit; and to protect it completely would require it to be applied to all the practical uses of which it is capable, which could only be effected by means of many inventions. Further, the faculties of invention and discovery are rarely united in one man, and it requires a higher quality of mental power to make a discovery, than to apply that discovery to useful purposes by means of invention.

Scientific discoveries, being of universal utility, like the light, the land, the air we breathe, belong, by their very nature, to all the nation. From the moment that a discovery is published, it gets copied into all the scientific publications; it immediately becomes used by teachers for the purposes of instruction, and by inventors generally as a basis for patentable inventions; and in these ways it becomes at once national property, and no law can prevent it.

It may also be objected that scientific men should not make discoveries if there is no payment for such labour. Many men are impelled by a natural desire to do good, irrespective of payment, whilst others are equally selfish, and live upon the labours of their fellow-creatures; and if such men did not make discoveries we should be without most of the luxuries, comforts, and conveniences of life. Every man who benefits his fellow-men, or labours for the good of the nation, is entitled to means of existence, and the only just course is to provide for his support.

It may further be objected that scientific men should keep their discoveries secret; but that would be worse than useless, because discoveries cost great skill and labour, and when published are of great value to mankind.

The general aspect in which science is viewed by many persons in this country is that of a refined intellectual pursuit, which may be encouraged and honoured for the purpose of maintaining the tone of society, but which must on all occasions be considered as secondary to the more *apparently* practical requirements of national life, and be sacrificed to them; but this is a superficial idea, and has its origin in the low state of scientific knowledge. Science is eminently practical; scientific discovery lies at the very basis of national progress, and is the origin of many of the practical advantages of civilised life. The idea of men being able to honour demonstrable truth is simply an ignorant conceit. Science cannot be honoured by anyone, and the question is, not whether the State shall encourage science as a refined intellectual occupation, but whether our governments will consider the welfare of the nation in its relation to science.

One of the first duties of a Government is to protect its subjects in the enjoyment of their property; but as no law can reserve to discoverers the fruits of their industry, and as scientific discovery is national work, it is clearly a duty of the state to pay for it. It is as certainly its duty to provide and pay for original research as for its military and naval establishments; because the development of the industry and warlike appliances of the nation is quite as important as the maintenance of its means of defence and aggression. The power that has brought into existence new industries is certainly as valuable to this nation as the means of preserving to us the possession of them afterwards; and we must not forget that our great cannon, explosive missiles, and armour-plated ships would not have existed but for the discoveries of scientific men.

Since the last Paris Exhibition an opinion has gradually spread that, in consequence of our neglect of science, foreign nations are supplanting England in her manufactures; but whether this opinion is or is not correct, there can be no doubt that national superiority can only be maintained by being first in the race, and that as a matter of prudence we should not neglect any precaution which is necessary to the welfare of the nation.

The very foundations of science in this country are rapidly being destroyed by the neglect of science by our Governments, and by those who have derived the greatest amount of benefit from it. Original discovery is the basis of all scientific progress. Great discoverers are rare, and the loss of a few of them is a national calamity. The majority of our most able investigators have ceased to make researches because the State does not pay for such labour. Several, also, of our most eminent discoverers have died, and others have not arisen to take their places. The discoveries in chemistry by British chemists, published in the *Journal of the Chemical Society*, have diminished almost to zero; whilst those of foreign chemists have so increased that the journal referred to is almost filled with them. But few first-class investigators are making original researches in this country, and we are rapidly becoming dependent for our progress in scientific arts and manufactures upon knowledge supplied to us by foreign nations.

In all directions, wherever we examine the state of knowledge of science amongst the governing men of this country, we find it very defective, and attended by results

seriously injurious to the welfare of the nation. Gentlemen who are comparatively ignorant of science are appointed by our Governments to decide scientific questions. Only recently (May 21st, 1872), a memorial of the British Association, signed by the eminent president, Sir William Thomson, was sent to the Lords of the Treasury, applying for a sum of £150, to continue a series of observations on the tides, upon which the Association had already expended £600 from its own resources, and which was essential to a more complete knowledge of the tides, and consequently to the greater safety of our navy. The reply to this application was most civil; but, putting upon it the most charitable construction, it exhibited a degree of ignorance of the national value of science most painful to contemplate. The reply stated "that their lordships have given their anxious attention to the memorial, and that they are fully sensible of the interesting nature of such investigations; but that they feel that, if they acceded to this request, it would be impossible to refuse to contribute towards the numerous other objects which men of eminence may desire to treat scientifically. Their lordships must, therefore, though with regret, decline to make a promise of assistance towards the present object out of public funds."

Here was a subject of great importance to the national welfare, and which it was the duty of the State, and not that of the British Association, wholly to pay for, treated as if it was only an investigation of an "interesting nature," "which men of eminence may desire to treat scientifically."

Their lordships were apparently not aware that ignorance of the course and height of tides often leads to shipwrecks, and that their refusal of £150 might lead to the loss of some valuable ship; they seemed to have forgotten that the loss of the ill-fated *Captain* was due to neglect of science. Such a want of knowledge in any private appointment would be a sufficient reason to remove from his post the responsible person. It is difficult to believe that the Government of a maritime country should be so ignorant of science as to decline to make even a promise of assistance out of the public funds of the small sum of £150 for such an important purpose, whilst it expends immense sums of money upon ships. Their lordships were manifestly unable to appreciate the importance of the application, or to perceive the duty of the State to pay for such labours; and, instead of acting upon the opinion of disinterested men, of the highest eminence in the subject, declined to accede to the request.

Gentlemen who are but little acquainted with science are also appointed by our Government to direct eminent scientific men in scientific matters, and the results, as might be expected, are most unsatisfactory. A recent melancholy instance of this kind, which has degraded our Government in the opinion of other nations, and of all well-instructed persons, is fresh in the memory of the public. Mr. Ayrton, the Chief Commissioner of Works, was placed in authority over the eminent botanist, Dr. Hooker, at Kew Gardens, and presumed to interfere with the management of the hothouses under Dr. Hooker's care. There is scarcely a scientific man in this country who has not frequently suffered from similar ignorant misdirection, but the circumstances have not happened to become public. If governing men possessing the requisite knowledge of science for such posts cannot be obtained, it is clear that those appointed should not be entrusted with the power, nor burdened with the responsibility of directing subjects they do not understand, and the course indicated in such a case is a division of labour, making the scientific officers much more independent than they hitherto have been.

The origin of all these evils lies largely in the defective state of scientific instruction at our old universities and great public schools. Our governing men, having been chiefly educated at those institutions, have been but little instructed in science. In addition to this, science has advanced so greatly during the last few years that it has

become an immense department of national life, requiring a special education to understand, and has left our old institutions behind.

The heads of colleges and the head masters of nearly all our grammar schools, having also acquired their learning at our old universities, have been but little, or not at all, educated in science, and in consequence of this, scientific instruction is in a low state throughout nearly the whole scholastic system of the country. Further, the "Endowed Schools Commission," now pursuing its labours, recommends "that all lecturers and teachers" in the various Government schools of this country "shall be appointed and dismissed by the head masters," and that "the said head masters shall have under their control the choice of books, and the method of teaching" in those schools. A result of these provisions will be that the system of appointing gentlemen comparatively ignorant of science to direct teachers of science will be continued, and scientific instruction will continue to be degraded in the grammar schools of this country. These very proposals prove that the gentlemen who made them had not been well instructed in science.

It is manifest that the only foundation of a reliable judgment in scientific affairs is a good knowledge of science, and this can only be obtained by long-continued study and experience. It is also clear that the practice in this country of appointing gentlemen comparatively ignorant of science to legislate for it, and to direct scientific men in Government offices and public schools, is one of the most effectual that could be devised for retarding the progress of the nation in all those matters which depend upon science. If scientific men are to be legislated for and directed, justice requires that it should be by men possessed of adequate scientific knowledge.

To partly remedy this unsatisfactory state of things, we require a State Minister of Science, possessed of scientific knowledge and good administrative ability; a Scientific Council, to advise the Government in all important matters relating to science; and State laboratories for pure scientific research.

The funds for providing State laboratories already exist; the sum of nearly £600,000 has accumulated in the form of fees received by Government for the granting of patents for inventions; and as the discoveries made by scientific men form the materials by means of which those inventions were made, the money thus accumulated may be justly claimed by scientific discoverers as a source from which their labours should be remunerated by the State.

As long as scientific men continue at their own expense to do scientific work which ought to be paid for by the State, so long will the governing and richer classes of this country, impelled by the selfishness which pervades them in common with nearly all mankind, and unenlightened by knowledge of science, neglect the duty of paying for original research, and reap the chief benefits of such labours.

The time has arrived when this great national evil should be made known, and put an end to; and our men of science should present a memorial to our Government, claiming as a matter of justice, necessary for the nation's welfare, that the accumulated fees from patents should be applied to the establishment of a Scientific Department of the State, the erection of State laboratories, and the payment of discoverers for the national work of research.

Should our Government continue to neglect these just claims, and disregard the evidence collected by the "Royal Commission for the Advancement of Science," the decline of original scientific research, which has already commenced, will continue. The probable results of this will be, inventions will become scarce; new trades will not be developed; improvements in agriculture, arts, manufactures, means of defence, and other important matters, will decline; the value of houses and land will diminish; and our commerce will pass into the hands of other nations.

ON THE HISTORY OF OZONE.*

By Professor ODLING, F.R.S.

THE most important points in the history of ozone are the following:—I. Its recognition as a distinct variety of matter or substance, by Schönbein in 1840. II. An inquiry into its nature, made by Marignac in 1845, whereby it was established that the action of ozone on various substances results simply in their oxidation. III. The evidence of different kinds, accumulated by many observers during a period extending from 1845 to 1863, that the matter of ozone is identical with the matter of oxygen. IV. The demonstration by Andrews and Tait in 1860, that ozone is a condensed form of oxygen. V. The recognition by Andrews and Tait in 1860, and interpretation by the speaker in 1861, of the singular fact that, in certain cases, the removal of its constituent ozone from a mixture of ozone and oxygen in unattended by any alteration in the volume of the gas, notwithstanding the considerable oxidation effected by it. VI. The study of the quantitative reactions of ozone by Brodie in 1872; and his establishment of the relationship of ozone to ordinary oxygen, in corroboration of some less exact results obtained by Soret in 1865, as also of a suggestion made by the speaker in 1861.

I.

Ozone was discovered by Schönbein, in 1840, when experimenting with the then newly-invented battery of Sir Wm. Grove,—an instrument still recognised as yielding a current superior, in respect of joint quantity and intensity, to the current yielded by any other electromotor available for general use. Ozone was recognised by Schönbein successively as a minute constituent of the oxygen gas resulting from the electrolysis of water effected by a current of high tension; as a minute constituent of air or oxygen through which electric discharges have taken place; and as a minute constituent of air in which moist phosphorus has been undergoing slow oxidation. To Schönbein then is due the great merit of recognising ozone as a distinct form of matter, having an identity of its own by whatsoever means prepared—as also the merit of discovering the most important means for the production of ozone, and of establishing its principal properties and reactions.

The general properties of ozone are those of an active oxygenant. Thus, like chlorine and peroxide of nitrogen, it bleaches colouring matters, corrodes fabrics, tarnishes or otherwise attacks metals, and liberates iodine from iodide of potassium. Its special properties are its characteristic pungent odour, its destructibility by a moderate heat, and its non-manifestation of any acidulous reaction.

II.

The nature of ozone was at first the subject of much speculation, Schönbein inclining to the view that it was a new elementary body, and a component of nitrogen. But in 1845, Marignac, in a series of most exact experiments, made partly in association with De la Rive, brought the question as to the nature of ozone within a very narrow compass. The experiments of these investigators, in which they established, among other points, that by exposure to the action of ozone, moist silver was converted simply into oxide of silver, and iodide of potassium into its oxidised form of iodate of potash, were susceptible only of one or other of two interpretations—either the interpretation which they themselves put on their results, that the matter of ozone is identical with the matter of oxygen—or, else the interpretation put on their results by Schönbein, that ozone is constituted of oxygen *plus* the elements of water, or in other words, that it is a peroxide of hydrogen. For a long time, experiment seemed quite incompetent to decide between these two views—opposite conclusions being arrived at almost alternately by the

* Read before the Royal Institution of Great Britain.

different investigators engaged on the inquiry. Corroboration, however, if any were needed, of the fact that ozone is really formed from oxygen itself with or without water, and not from any trace of nitrogen or other foreign matter that might possibly be present, was afforded by a remarkable experiment conducted by Fremy and Becquerel in 1853, being, indeed, the first recorded quantitative experiment made with ozone. By passing a long series of electric discharges through a given volume of oxygen standing over an aqueous solution of iodide of potassium, MM. Fremy and Becquerel succeeded in causing the whole of this oxygen to assume the form of ozone; as was shown by its ultimate complete absorption by the solution, with correlative liberation of iodine from the dissolved iodide of potassium.

The difficulty experienced in those early days of making out the real nature of ozone—of ascertaining whether it is a form of oxygen or a peroxide of hydrogen—depended mainly on the very small degree to which it was then possible to charge air or oxygen with the ozone to be examined, and on the necessity for the exclusive employment in the investigation of apparatus in which neither metal nor organic matter was present for the ozone to react with. The apparatus had consequently to be constructed entirely of glass, and all the junctions to be made before the blow-pipe or by grinding. Now-a-days, by improvements in the methods of conducting the processes of electrification and electrolysis, it is possible to charge oxygen with ozone in very considerable proportion; while by means of paraffin, a substance on which ozone is without recognisable action, junctions of the glass apparatus employed may be made and unmade with the greatest facility.

III.

Assuming the ozone furnished by the three principal processes for its production to be one and the same substance, it was not until the year 1863 that the absolute freedom of ozone from any proportion of hydrogen was so definitely established as not to allow of any further question. In this year, Soret showed that although ozonised oxygen obtained by electrolysis, after having been desiccated as thoroughly as possible, frequently yielded some water as a product of its decomposition by heat, yet that when certain precautions were taken, and certain sources of error in the production and collection of the electrolytic oxygen were recognised and avoided, a uniformly negative result was obtained, and not a trace of moisture or other compound of hydrogen resulted from the decomposition by heat of the ozone present in the oxygen.

This conclusion of Soret's was confirmatory both of the previous result of Andrews with regard also to electrolytically obtained ozone, and of the yet earlier result of Schönbein himself with regard to the ozone obtained by the slow oxidation of moist phosphorus. For in opposition to the view enunciated first by himself, and in seeming discrepancy with the undoubted fact that for the production of ozone by means of phosphorus the presence of moisture is essential, Schönbein, in 1849, showed by repeated experiment, that when ordinary air in quantities of several hundred litres, ozonised as strongly as possible by its passage over moist phosphorus, was transmitted first through a desiccating tube, then through a tube heated to 400°, so as to effect the destruction of the ozone present, and finally through another desiccating tube to absorb any moisture that might result from the destruction of the ozone, this last desiccating tube did not show, by an increase of weight or other change, any absorption of moisture whatever, notwithstanding the largeness of the absolute quantity of ozone destroyed in the experiment. From this time forth, Schönbein abandoned the notion of hydrogen being a constituent of ozone; and while making a valid distinction between his own view and that of Marignac and De la Rive, admitted with them that the matter of ozone is identical with the matter of oxygen. These last-named investigators, in their research already referred to (1845), showed that perfectly dry oxygen, sub-

mitted to the influence of electric discharges, experienced an alteration of character, whereby it acquired the property of liberating iodine from moist iodide of potassium,—a result afterwards confirmed by Fremy and Becquerel. But they did not regard this alteration of character as due to the formation in small proportion of a new substance within the mass of oxygen, but rather to the assumption by the mass of oxygen of a peculiar electric condition. Moreover, the fact of dry oxygen being capable of some modification by the action of electric discharges, coupled with the fact of the inability of the so modified oxygen to act upon iodide of potassium save in the presence of water, was not inconsistent with the notion of this modified oxygen having to unite with water in order to produce a compound identical with the ozone obtained immediately from moist or watery reagents. That the effect of electrical discharges, and more particularly of the silent discharge, on perfectly dry oxygen, is really to convert a small proportion of this oxygen into ozone identical with that furnished by electrolysis, and capable of acting upon certain substances, as mercury and iodine, when in the dry state, and on certain other substances, as iodide of potassium and metallic silver, only when in the moist state, was first put beyond question by Andrews and Tait, in a research next to be considered.

IV.

In the spring of 1860, Dr. Andrews and Professor Tait made a joint communication to the Royal Society on the volumetric relations of ozone. The primary object of this research was to ascertain whether any, and if so what, alteration of volume took place in the conversion of a given quantity of oxygen into ozone. They thus attacked the problem from an entirely new point of view, and, with admirably directed pains and skill, succeeded in making probably the most important contribution hitherto made to an exact knowledge of the nature of the ozone. In their experiments, a quantity of perfectly pure and dry oxygen, contained in a straight glass tube with a pressure-gauge appendix, was ozonised by means of the silent electric discharge passed through the gas for some time. Coincidentally with the passage of the silent discharge through it, the quantity of gas contained in the glass tube was observed to undergo a marked contraction in volume. This contraction proceeded at first rapidly, but afterwards more slowly, till it attained a limit which, in one of their experiments, was estimated at one-twelfth the original volume of the gas. And as whenever the gas, contracted in this manner, was examined, it was found to be proportionately ozonic, the general fact was established that the production of ozone from ordinary oxygen is attended with a contraction in volume. The converse result was also obtained. It was found that when oxygen, contracted by the passage of the electric discharge, was exposed for a short time to the temperature of 270°—300°, it was restored to its original volume. And as whenever the gas, re-expanded in this manner, was examined, it was found to be free from ozone, the general fact was established that the conversion of ozone into ordinary oxygen is attended with an expansion in volume. And this alternate contraction of a given quantity of oxygen by exposure to prolonged electrification, with production of ozone, and re-expansion of the gas to its original volume by exposure to a temporary heat, with destruction of ozone, could be repeated an indefinite number of times. Now the only possible conclusion to be drawn from these experiments would appear to be that, the matter of ozone being identical with the matter of oxygen, ozone is oxygen in a denser form,—that is to say, in the form of a more complex unit. Some years afterwards, this conclusion was confirmed in a very interesting manner by Professor Tyndall, in the case of ozone obtained electrolytically. He found that the absorptivity for radiant heat of electrolytically obtained oxygen, when rich in ozone, was upwards of a hundred times greater than that of ordinary oxygen—a result indicating ozone to have a more complex molecular constitution, and consequently a greater density, than

ordinary oxygen. Moreover, after this same electrolytically obtained and richly ozonic oxygen had been subjected to the action of heat, so as to have its ozonic character destroyed, it then exhibited merely the absorptivity for heat of ordinary oxygen,—the observed absorptivity not going at all beyond that of ordinary oxygen, as would have been the case if the ozone originally present in the electrolytic gas had been decomposed into ordinary oxygen and aqueous vapour.

Referring to the statement already made, that in Messrs. Andrews and Tait's experiments, the oxygen gas, more or less contracted by the electric discharge, was found to be proportionately ozonic, this point was ascertained in the following way:—A small thin glass bulb, containing a solution of iodide of potassium, was introduced into the oxygen-holding tube, prior to its being filled with the gas; which, after having been more or less contracted by the process of electrification, was next submitted to the action of the solution, released on the breaking, effected by concussion, of the small bulb wherein it was contained. And on estimating the quantity of iodine set free from the iodide of potassium solution by its reaction with the contracted gas, it was found to be the exact chemical equivalent of a weight of oxygen equal in volume to the amount of contraction which the original gas had experienced during the process of electrification; so that if in the process of electrification, there had been 1, 2, or 3 c.c. of contraction, the quantity of iodine liberated was chemically equivalent to the weight of 1, 2, or 3 c.c. of oxygen; whence it results that to ascertain the iodine-titre of the ozonised gas is to learn the contraction of the original gas effected by its electrification, or the correlative expansion of the electrified gas effected by its exposure to heat. In the case also of electrolytically obtained ozonised oxygen, it was shown firstly by Andrews and Tait, and subsequently by Soret, that the iodine-titre of the gas is the measure of its expansion by heat, consequent on the conversion of its constituent ozone into ordinary oxygen.

(To be continued.)

RESEARCHES ON THE PART WHICH SULPHUROUS ACID PLAYS WHEN EMPLOYED FOR THE SACCHARIFICATION AND SUBSEQUENT ALCOHOLISATION OF GRAIN, ACCORDING TO A NEW METHOD.

By V. HEMILIAN and N. MELNIKOFF.

DURING the last few years, a process has been introduced in the distilleries of Russia and Southern Germany, Bohemia, and other portions of the Austro-Hungarian Empire, which is considered by practical distillers to increase the yield of alcohol obtainable from grain, including maize, and which consists in the use of a weak solution of sulphurous acid when applied during the diastatic saccharification.

The raw grain and malt, previously ground to a fine powder, are macerated for from five to six hours in a cold solution of sulphurous acid, after which the mixture is heated to from 70° to 75°, and treated as usual. While there is no doubt that this practice is really good, the action of sulphurous acid on the substances capable of yielding alcohol has never been scientifically elucidated; we have made researches relative to this action, and here publish the principal results of our experiments.

In the first place, we have found, by a series of experiments, that sulphurous and other acids, employed in small quantities in practice, have the effect of very perceptibly diminishing the saccharifiant power of diastase, and, as a consequence of the application of the new method of saccharification, the action of a portion of the malt employed is rendered useless; but, on the other hand, our experiments have proved that sulphurous acid, applied in quantities to

be hereafter indicated, renders the starch of the meal, when macerated in it for a long time, more fit for conversion into glucose. It is probable that sulphurous acid, during the process of maceration, dissolves slowly the gluten and other albumenoid substances which envelope the starch in the meal, and thus the immediate contact of the starch granules with the solution of the diastase is promoted during the saccharification.

The effect produced by the action of the sulphurous acid consists, therefore, in the difference of the two opposite actions, one of which is injurious to alcoholisation, by decreasing the saccharifiant power of malt, while the other favours a more complete intervention of the starch of the substances employed. This difference, which determines the increase in the quantity of glucose, depends directly on the duration of the cold maceration, and on the quantity of sulphurous acid employed. The largest quantity of glucose is obtained by causing the cold maceration to continue for five or six hours with a solution containing from 0.1 to 0.13 per cent of the quantity of malt and meal used.

When the duration of the cold maceration is prolonged, and the quantity of sulphurous acid diminished, the quantity of glucose obtained is increased to its maximum. When the maceration in cold water, without sulphurous acid, is continued for eighteen hours, the result is equal to that obtained by the use of macerating with cold sulphurous acid solution; but maceration in cold water only is sure to bring on acidification and incipient putrefaction, which is not the case when sulphurous acid is present. If, on the other hand, the quantity of sulphurous acid is increased, and the time of cold maceration decreased, the quantity of glucose obtained rapidly decreases, because the injurious influence of the sulphurous acid upon diastase then begins to predominate over its favourable action upon the meal.

The increase in the yield of glucose, under the action of sulphurous acid and the most favourable conditions, is found to vary from 2 to 3 per cent of the weight of the grain employed. No sulphuric acid is formed during the cold maceration alluded to; the sulphurous acid forms, with the macerated materials, combinations from which, by the application of mineral acids, the sulphurous acid is set free without simultaneous precipitation of sulphur, so that no formation of hyposulphites takes place. The colouring matter of malt is, moreover, destroyed by the cold maceration with sulphurous acid; and, since we have found that the combinations formed by sulphurous acid during the cold maceration do not perceptibly injure the saccharifiant property of diastase, we propose the following modification in the application of this method. The meal only, without malt, is macerated in the cold with the solution of sulphurous acid of the strength above mentioned, and then heated to 50°, so as to volatilise any free sulphurous acid. The malt is next added, and the mixture, being all the time well stirred, is heated to from 70° to 75°, these temperatures being best suited for saccharification. As regards the action of sulphurous acid upon the process of fermentation, comparative experiments have proved that this acid, in free state, even in so small a quantity as 0.2 per cent of the sugar, very perceptibly hinders the alcoholic fermentation which is rendered very slow, while the combinations formed by the sulphurous acid during the maceration, do not at all effect the ordinary course of the fermentation, which continues regularly until all the glucose is spent. During the fermentation of the wort obtained by the new method, and application of sulphurous acid, sulphuretted hydrogen is evolved in small quantity mixed with carbonic acid, while, in the fermenting liquid, sulphur compounds are formed which it would be very interesting to study more minutely. It is very important, for practical purposes, to know that, in wort fermenting under the conditions just mentioned, almost twice as little free acid is formed than in the fermentation of grain, malt, and meal under the ordinary conditions. The utility of the sulphurous acid process is

rendered very apparent when it is borne in mind that the free acids alluded to are formed at the expense of alcohol, while, at the same time, by the decrease of acids the nutritive value of the spent wash is rendered greater, and its consumption by cattle improved because it is rendered less injurious to health.—*Moniteur Scientifique*.

NOTE ON THE PURPLE OF CASSIUS.

By H. DEBRAY.

WHEN a solution containing simultaneously protochloride and bichloride of tin, is poured into a very dilute solution of chloride of gold, the result is the formation of a brown-coloured fluid which is turbid when seen by reflected, and purple when seen by transmitted, light; while after a time a coloured precipitate is deposited in the liquid, which is the so-called purple of Cassius, and is—as is well known—the basis of all gold pigments employed in glass and porcelain staining for the purpose of producing rose, red, and violet colours.

The purple of Cassius may also be obtained under other conditions, and its composition varies with its mode of preparation, but is always such that it (the purple) may be represented as consisting of hydrated binioxide of tin and metallic gold in very finely divided state. The colour of this substance is the deeper the more gold it contains, but does not differ from the hues which the precipitation of gold alone can produce, so that Macquer, who first made this observation, viewed the purple of Cassius as a mixture of gold and hydrated binioxide of tin. Proust having observed that the purple dissolves in ammonia while still wet, and that on being triturated with mercury it yields no gold, the mixture hypothesis was generally abandoned, and the purple considered to be a chemical combination. The only rational mode of viewing the composition of this combination was to consider it to be a saline oxide, that is to say, a stannate of protoxide of tin and suboxide of gold, the latter containing a sufficient quantity of oxygen to convert the protoxide of tin into binioxide. This saline oxide might, moreover, be mixed with a variable proportion of stannic hydrate (*hydrate stannique*).

Since Proust's days, there have been many discussions and more researches on the constitution of the purple of Cassius. It would be impossible to give a *résumé* of these labours here; suffice it to say that no decisive arguments or any new view has been published in favour of either of the two hypotheses just alluded to, and which in my opinion are quite erroneous. I consider the purple of Cassius to be a lake of stannic (or metastannic) acid coloured by very minutely divided gold. The colouring matter of this lake has become insoluble in its usual solvent, mercury, just as the fast colours of the dyer resist the action of water in consequence of their union with the fibres of the woven fabrics, or with the mordants. The following results of experiments, and explanation of facts discovered by me will, I hope, completely justify this mode of viewing the purple of Cassius. I boil together a mixture of solutions of bichloride of tin and acetate of soda; the result is that binioxide of tin is precipitated. I next pour into the hot liquid a small quantity of chloride of gold, and then some oxalate of potassa; the result of which is that the gold is immediately reduced, and while only a small quantity of the metal is precipitated on the glass, the bulk of it is precipitated upon the oxide of tin, which thereby assumes the ordinary colour of the purple of Cassius. A perfectly similar colour can be produced with alumina by precipitating gold in a fluid which contains alumina in a state of suspension. For this purpose, I add to a solution of chloride of gold, saturated with acetate of soda, gelatinous alumina, and to the hot mixture I add gradually oxalate of potassa, whereby the gold is reduced. These two lakes having been kept suspended in water and shaken up in a closed strong glass vessel for several hours with mercury, have not lost their colour.

The ordinary method of preparing the purple of Cassius does not evidently differ from that just alluded to, except that the oxide and the colouring matter are precipitated together, by which means the beauty of the colour is undoubtedly increased, as well as its fastness towards mercury. It now remains to be explained how it is that this lake is soluble in ammonia. We know that oxide of tin is soluble in ammonia when precipitated at the ordinary temperature, so long as the oxide continues wet, and that it ceases to be soluble in ammonia under various conditions, as for instance, an elevation of temperature, and more particularly drying. The purple of Cassius loses its solubility in ammonia under precisely the same conditions, and hence it ought to be observed that the solution of purple of Cassius in ammonia (that solution being always turbid when viewed by reflected light) deposits slowly metallic gold, while the oxide of tin remains almost entirely in solution. This well-known fact is quite natural if the purple is a lake, but it is very difficult to explain if the gold is in the state of oxide, because the action of ammonia on the metallic oxides of the precious metals gives rise to the formation of more or less complex products, but never sets the metal free.

Mercadieu has observed that in the assay of the precious metals when silver which contains a small quantity of tin and of gold is dissolved in nitric acid, a substance is obtained very analogous to the purple of Cassius; and since gold is not oxidised by nitric acid, he inferred that the purple of Cassius contain the gold in the metallic state. Gay-Lussac having resumed these researches came to the same conclusion, but since this purple of Cassius so formed was not soluble in ammonia, it became necessary to demonstrate the identity, or at least the isomerism, of the two purples, Gay-Lussac feeling inclined to admit isomerism between the two substances. It can be proved that no other difference exists between the two purples except that due to the difference of conditions under which the binioxide of tin is formed. The oxide of tin obtained by the oxidation of that metal by the aid of heat is insoluble in ammonia, and the same holds good for the lake which it forms with gold. But if the ternary alloy of silver, gold, and tin is acted upon at a gentle heat, a purple is obtained which is soluble in ammonia, and I have found, by direct experiment, that the oxide of tin obtained under these conditions is soluble in that reagent.—*Comptes Rendus*.

THE CHEMICAL EQUIVALENT OF ETHER.*

By H. F. WALLING, Professor of Civil Engineering in Lafayette College.

SUPPOSING the ether of space to be a gas, and therefore that it must have an atomic weight or chemical equivalent, I have thought that under the dynamic theory of gaseous elasticity this atomic weight could be computed in a simple manner whenever certain data should be sufficiently well determined, and that even now a tolerable approximation may be attained

$$\text{In the equation} \\ WV^2 = CT.$$

Let W represent the weight of an atom or molecule of any gas, V the velocity of an acoustic wave in this gas, and T any temperature reckoned from absolute zero in degrees which represent equal accessions of energy to the gaseous atoms or molecules. Then will C be constant, or nearly so, for all gases at temperatures considerably above that of their liquefaction.

To prove this we have first to show that V^2 changes in a constant ratio with T in any gas, W remaining constant.

Now the velocity of an acoustic wave is ascertained by calculating the velocity acquired in falling a distance

* Read before the American Association at Indianapolis.

equal to one-half the length of a homogeneous column of the gas having a sufficient height when vertically placed to produce by its own weight a pressure equal to that maintained in the gas. The velocity thus found is multiplied by a coefficient, constant for all gases and at all temperatures.† Since the height of the balancing column is, according to the law of Gay-Lussac, proportional to the absolute temperature, and since the square of the velocity acquired in falling is in proportion to the height of the fall, V^2 maintains a constant ratio to T , and C is constant so long as W remains unchanged.

Moreover, since the densities of different gases, at common temperatures and pressures are proportional to their atomic weight, the heights of their balancing columns, and therefore V^2 must be *inversely* proportioned to W . Hence the product WV^2 is the same for all gases having a common temperature, and hence C is constant for all gases at all temperatures considerably above liquefaction.

Assuming for hydrogen that $W=1$, and taking the velocity of sound in that gas at zero centigrade to be 4164 feet per second, as determined by Dulong, we have

$$(4164)^2 W = 273C,$$

zero centigrade being equal to 273° of absolute temperature. Whence $C=63512$.

A luminiferous wave is generally supposed to be similar in its nature to a sound wave. If this be true, the general equation with C as above determined will apply to the ethereal medium.

The velocity of light is, in round numbers, 1,000,000,000 feet per second, which gives—

$$(1,000,000,000)^2 W = 63512T,$$

in which T represents the temperature of the interplanetary spaces. Hopkins places it at 38.5° C., Fourier at -50° , and Pouillet at -142° .†

The values of W calculated for ether with these values of T are as follows:—

$T = -38.5^\circ = 234.5^\circ$ absolute temperature,

$W = 0.00000000014893564$.

$T = -50^\circ = 223^\circ$ absolute temperature,

$W = 0.00000000014163176$.

$T = -142^\circ = 131^\circ$ ab. temp., $W = 0.00000000008320072$.

Taking the mean of the estimated temperatures,

$T = -77^\circ = 196^\circ$ ab. temp., $W = 0.00000000012448352$.

Comparing the values with the fraction—

$$\frac{1}{273} = 0.00000000014551912$$

it appears that the atomic weight of ether is probably equal to that of hydrogen after it has undergone not less than 36 or more than 37 successive halvings.

Perhaps an objection will be made to this conclusion that the transverse vibrations, which constitute light, indicate that their medium is solid rather than fluid, and therefore that the relations between its atomic weight and wave velocity is different from that of gases.

I have advanced the supposition in previous papers that the atoms of bodies, in consequence of their momenta and mutual attraction, fall into a linear arrangement; that the "elemental fibres" thus constituted intersect each other so as to occupy space in its three dimensions, forming the edges of imaginary cubes in gases; that the atoms being *non-impenetrable* traverse freely each line of fibre in both of its directions, tending to preserve equality

of distances by mutual attractions, and the accelerations produced by temporary huddlings; and that longitudinal vibrations, along the fibre (condensations and rarefactions) in consequence of the mutual actions and reactions of intersecting fibres, are accompanied by transverse vibrations (undulations), which in ether constitute light, the resultant impulses being radial for the longitudinal and concentric for the transverse vibrations.

If such a hypothesis be found tenable, it will remove any objection to the above conclusion founded upon a supposed constitutional dissimilarity between ether and ordinary gases.

ON THE PRESENCE OF DIDYMIUM IN CERTAIN SPECIMENS OF PYROMORPHITE.

By CHARLES HORNER.

It will be remembered that I drew attention to the fact of the presence of didymium in a specimen of pyromorphite from Cumberland (see CHEMICAL NEWS, vol. xxvi., p. 109, and Professor Church's note thereon, p. 130). Lately, through the courtesy of Professor Maskelyne, I have been enabled to examine other specimens of the above mineral in case 60 at the British Museum, and found that most of the specimens from Loughton Gill, Cumberland, contained this rare element. I likewise detected the absorption lines of didymium in some very elegant specimens of pyromorphite from Wheal Alfred, Cambourne, Cornwall, and in others from the Vale of Towy, Caermarthenshire.

Mortlake, December, 6, 1872.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 5th, 1872.

DR. FRANKLAND, F.R.S., &c., President, in the Chair.

WHEN the minutes of the previous meeting had been read and confirmed, Messrs. F. W. Fison and T. A. Ormerod were formally admitted Fellows of the Society.

The donations were then announced, and the names of Messrs. George Washington Arnott, James Scott McGregor, and Cornelius A. Mahony read for the first time; for the third time, Messrs. Kigonari H. Yoshida, Francis H. Hobler, Sydney Lupton, E. W. Prevost, Ph.D., Thomas Williams, T. D. Titmal, Joseph Lainson Wills, A. Percy Smith, Philip Braham, John Hollings Mitchell, M.A., Robert William Jones, and A. Cameron Bruce, M.A. who were balloted for and duly elected.

The first two papers "*On Hypophosphites*," and "*On the Reducing Power of Phosphorus and Hypophosphorous Acid and their Salts*," by C. Rammelsberg, were read by the Secretary. In the first paper the author, after mentioning the labours of Rose and Wurtz on this subject, gives a detailed account of the crystalline form, amount of water of crystallisation, and mode of decomposition by heat of the numerous hypophosphites which he had examined, five of which, namely those of sodium, lithium, thallium, cerium, and uranium, had never before been noticed. The results of his experiments show that the hypophosphites of thallium, calcium, cadmium, and lead have no water of crystallisation; those of sodium, lithium, barium, strontium, manganese, and uranium one molecule; whilst those of magnesium, zinc, nickel, and cobalt have six. They are all decomposed by heat, evolving a mixture of hydrogen and phosphoretted hydrogen, which is sometimes spontaneously inflammable and sometimes not, leaving a residue which in most cases consists of a mixture of pyrophosphate and metaphosphate of the metal; but the

† This coefficient as found by experiment is $\sqrt{142}$, and it represents the amount of acceleration which is produced by the disturbance of temperature developed in the condensation and rarefaction of the wave. The cause and amount of this acceleration was first indicated by La Place; $\frac{142}{100}$, the square of the above coefficient being the

ratio of the amount of heat expended, including the *external work* done when a gas is heated and allowed to expand under a constant pressure, to the amount expended to produce an equal elevation of temperature, when no external work is performed, the volume remaining constant. It is now believed that the same coefficient applies to all gases whose powers of absorption and radiation are inconsiderable.

† Nichol's Cyc. of Physical Science. Art. Temperature.

residue of the uranyl salt contains phosphide in addition, whilst the nickel and cobalt salts leave a mixture of metaphosphate and phosphide.

In the second paper, mentioned above, the author finds that the ultimate action of phosphorous acid on silver and copper salts is to precipitate the metal whilst hydrogen is simultaneously evolved. Barium hypophosphite with silver salts, and hypophosphorous acid with copper salts, likewise reduce the metal and evolve hydrogen, the acids in both cases being oxidised to phosphoric acid.

Dr. FRANKLAND in asking the members to return their thanks to Professor Rammelsberg for his interesting communication, said that the investigation of these compounds of phosphorus must be welcomed by all chemists. Some important theoretical points presented themselves for discussion, as to the way in which the hydrogen was placed, and the cause of the phosphoretted hydrogen evolved being in some instances non-spontaneously inflammable, and in others spontaneously inflammable, the latter being probably occasioned by the presence of traces of the liquid phosphoretted hydrogen, P_2H_4 .

Mr. VERNON HARCOURT said that in studying the action of heat on such substances, although they were pure, well crystallised, and homogeneous, we were experimenting under circumstances of a very varying nature. If it were possible to heat the whole of a substance simultaneously to the same temperature, we should probably obtain only one result, but as it was most likely that the substance had been rapidly heated, every part had not been exposed to the same temperature, so that sometimes spontaneously inflammable phosphoretted hydrogen was obtained and sometimes not. In order to study the circumstances under which these different phenomena occurred the subject would need to be very carefully examined.

Professor WILLIAMSON remarked that one of the great difficulties in the experiments on the action of heat on the substances described by Professor Rammelsberg, was that one portion of the substance would necessarily be heated in the products of decomposition of another, that is some of the molecules would be decomposed whilst others were heated in a current of the products of decomposition. This, however, was not the only difficulty, for, to take a common case, viz., the action of heat on chlorates, here we have most of the molecules giving off oxygen, but others are simultaneously taking up oxygen to form perchlorates. From a dynamical point of view, we should not expect that individual molecules would have different rates of vibration and therefore behave differently, but the fact remained that some molecules did behave differently from the others.

The PRESIDENT said that he inclined to the opinion that there were very few cases of chemical action where but one product was produced, even under the most favourable and uniform circumstances—that of two gases mixed by diffusion and then exposed to the action of light; there was always some variety of action.

The next paper on "*New Analyses of Certain Mineral Arseniates and Phosphates*," by A. H. CHURCH, was then read by the author. It contained numerous and carefully made determinations of the composition of six minerals.

Apatite.—In the pure crystals of apatite, from Murcia in Spain, the author finds nearly 1 per cent more tricalcic phosphate than corresponds to the formula Ca_3PO_4F , while there is a deficiency of nearly 2 per cent in the calcium fluoride.

Arseniosiderite.—By a series of analyses of a singularly pure specimen of this mineral, the author establishes the formula $5CaO, H_2O, Fe_2O_3, 3As_2O_5, + 3Fe_2O_3, 2H_2O$. It is remarkable that the ferric hydrate, $3Fe_2O_3, 2H_2O$, resembles arseniosiderite very closely, it is known as xanthosiderite.

Childrenite.—Numerous analyses have been made of this mineral, the formula—

corresponding well with the analytical results.

Ehlite.—The author gives the analyses of three specimens of this mineral from Cornwall, deducing from them

the formula $3CuO, P_2O_5 + 2CuH_2O_2 + aq$. This expression exactly corresponds among the phosphates to that for Cornwallite among the arseniates, the latter mineral having been previously shown by the author to have the formula $3CuO, As_2O_5 + 2CuH_2O_2 + aq$. Professor Church's conclusions as to this Cornish phosphate of copper were published in abstract in the CHEMICAL NEWS.

Tyrolite.—The author finds this species, like chalcophyllite, which it much resembles, to be strongly hygroscopic. The calcium carbon which it contains is proved to be integral and essential part of the mineral, the formula becoming—

Wavellite.—Some pure samples of this mineral from one of the localities near Cork were examined. It would appear that there are only $11H_2O$ and not $12H_2O$ in this mineral. When dried in *vacuo*, or at $100^\circ C.$, its formula thus becomes, if we reject the fluorine,—

The PRESIDENT thanked Professor Church in the name of the members of the Society for his contributions to our knowledge of these well-known minerals, and also for having supplied constitutional formulæ for some that had hitherto been destitute of them.

The last paper read was "*On the Condition of the Hydrogen Occluded by Palladium as Indicated by the Specific Heat of the Charged Metal*," by W. CHANDLER ROBERTS and C. R. A. WRIGHT, D.Sc. In this paper, which is a continuation of the one read before the Chemical Society on the 7th November, the authors give a detailed account of their experiments, and the methods employed in determining the specific heat of palladium, or of an alloy of palladium and gold, when charged with hydrogen by making it the negative pole in the electrolysis of acidulated water, and also of the uncharged metals. Assuming that a true alloy of the metal and hydrogen is formed, it would be easy, in accordance with Kopp's law, to calculate the specific heat of the occluded hydrogen. Since, however, the authors find that the specific heat of the occluded hydrogen calculated in this manner varies according to the amount of hydrogen present in the charged palladium—being as low as 0.4 when the palladium is fully charged, and as high as 0.9 when it is charged with a small volume of hydrogen—they infer that the palladium does not form an alloy with the occluded hydrogen, neither can it be regarded as a mixture of a definite palladium hydride with excess of palladium, as in that case either a constant value would be found, or the variation in the specific heat would be represented by a straight line and not by a curved one. The authors are therefore inclined to believe that in palladium charged with hydrogen each several charge must be regarded as giving rise to a distinct compound, and that palladium and hydrogen are capable of entering into combination in proportions which cannot be expressed by comparing simple multiples of the combining numbers of these elements respectively, that is, by simple formulæ.

The results of the experiments were illustrated by a carefully constructed curve.

The PRESIDENT said that the members would, doubtless, have great pleasure in according their thanks to the authors for their important communication on occluded hydrogen, and hoped that it would lead to an examination of the state in which the hydrogen was in this alloy or mixture. It would seem that it was not a definite compound of hydrogen and palladium, and therefore not in the state which the researches of Professor Graham had led us to suppose, and which had excited so much interest.

Mr. ROBERTS said they were somewhat disappointed that the results of their experiments did not favour the view that it was an alloy of hydrogen and palladium. He might state that the chief reasons why Professor Graham considered the hydrogen to be alloyed with the palladium were the calculated density of the hydrogen in the charged palladium, 0.733, taken in conjunction with its unimpaird

tensile strength, and its high electric conductivity. At the present time the relation between the hydrogen and palladium was very obscure, and could only be elucidated by a long series of carefully conducted experiments.

The meeting was then adjourned until Thursday, December 19, when papers will be read on the "Analysis of Water of the River Mahanuddy" by E. Nicholson, and "On the Polymerides of Morphine and their Derivatives," by E. Ludwig Mayor and C. R. A. Wright.

CORRESPONDENCE.

THE SALT THAT LOST ITS SAVOUR.

To the Editor of the Chemical News.

SIR,—In your "Notes and Queries" S. T. S. asks if the salt spoken of by Our Saviour was the chloride of sodium. The following personal experience may be interesting.

Some years ago I used salt as a manure on some land, a stiff clay, but interspersed with granules of carbonate of lime. Some of the salt was in hardish lumps, into which the small crystals had become concreted, something like a frozen mixture of ice and snow. These lumps were several weeks before they melted; and before they did so, as they lay on the soil, they lost the taste of salt and acquired that of carbonate of soda. I supposed this to be due to the joint action of the soil and atmosphere. I may add that the salt injured rather than benefited the soil, making it stiffer and wetter than it was naturally for several years.

Many years ago I read in the *Journal of the Royal Agricultural Society* an account of the beds of nitrate of soda in Chili. It was stated there that below the nitrate of soda was carbonate of soda, and below that, common salt. The writer supposed that these beds occupied the bottom of a dried-up salt lake, and that, by the action of the soil and air, the salt had been changed first into carbonate and then into nitrate of soda,—I am, &c.,

H. HIGHTON.

Putney, December 2, 1872.

MISCELLANEOUS.

London Drinking Water.—The following is the second of a series of monthly reports intended as a substitute for the return published by the Registrar General. It is interesting as exhibiting the London water supply at flood-time.

	Parts in a Million.	
	Free Ammonia.	Albumenoid Ammonia.
Kent Water Co. (Deptford Railway Station, 20th Nov.)	0'01	0'02
New River Co. (Cab Rank, Tottenham Court Road, 21st Nov.)	0'01	0'06
East London Co. (Cambridge Heath Gate, 3rd Dec.)	0'01	0'18
<i>Thames Companies:—</i>		
Chelsea Co. (Cab Rank, Horse Guards, 2nd Dec.)	0'02	0'13
West Middlesex Co. (Cab Rank, Portland Road, 3rd Dec.)	0'00	0'10
Southwark and Vauxhall Co. (Cab Rank, St. George's Road, 4th Dec.)	0'00	0'18
Grand Junction Co. (Cab Rank, Woodstock Street, 4th Dec.)	0'00	0'17
Lambeth Co. (Cab Rank, Palace Road, 2nd Dec.)	0'01	0'16

J. ALFRED WANKLYN.

Food Analyst for Islington.—Dr. C. Meymott Tidy, joint Lecturer on Chemistry, and Professor of Medical Jurisprudence at the London Hospital, has been elected Medical Officer of Health and Food Analyst for Islington.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, December 2, 1872.

In addition to a large number of original papers and memoirs relating to mathematics, hydraulics, mechanics, astronomy, physical philosophy, meteorology, physiology, and natural history, this number contains the following original papers and essays relating to chemistry:—

Practical Observations Relating to the Laws Deduced from the Boiling-Point Temperatures of Homologous Organic Compounds.—I. Pierre and E. Fuchot.—This memoir, elucidated by a large number of tables, refers to the correctness of the view held by scientific chemists as to the existence of a constant difference of the boiling-point of the homologous organic compounds, the formula of composition of which differs C_nH_{2n} . By carefully-conducted experiments, the authors prove that there does not exist a constant variation, and they find that two homologous substances, one of which contains more or less C_nH_{2n} , may exhibit, in the temperature of their boiling-point, differences varying from 10° to 35° , that is to say, a digression of $25\frac{1}{2}$ per cent.

New Combination of Bromine and Ether, Brominated Ether.—P. Schützenberger.—This compound is formed directly by addition (not substitution, for no bromhydric acid is given off) of bromine to ether, but the preparation, described at length, requires dexterous manipulation and pure materials. The brominated ether, below 0° , is a solid crystalline compound, $(C_2H_5O.Br)_2$, it is very deliquescent, although it remains solid even at 22° , its fusion-point. The combination is very unstable, being decomposed by the action of potassa, of zinc, and by a temperature of 100° , whereby bromhydric acid, water, bromide of ethyl, bromal, and a new substance, $C_2H_5Br_2O_2$, are formed, according to the following formulæ:—

Bromide of Bibromated ethyl. aldehyde.

Bibromated Bromal. Tribromated aldehyde. di-aldehyde.

Neutral Soap Free from Caustic Alkali.—M. Mialhe.—After first referring to some well-known technical details of soap-boiling, the author describes the process of treating soap-shavings with carbonic acid, whereby the caustic alkali present in soap is neutralised by being converted into a bicarbonate.

Anti-Fermentation Action of Silicate of Soda.—M. Picot.—This essay contains the detailed account of the results of a series of experiments, from which the conclusion is drawn that silicate of soda has the effect of arresting putrid fermentation, even when applied in small quantity. The author also states that the silicate of soda exerts marked physiological and therapeutical action.

Substance Extracted from the Fong-ling, *Pachyma pinctum*.—P. Champion.—The cryptogamic plant just named is found in China, and is used by the natives for the cure of certain forms of syphilitic disease. From this drug, the author, who has travelled through China, has obtained a substance, which he terms pachymose, insoluble in water and in ammoniacal copper solution, soluble in potassa, and then forming, with lime and lead salts, insoluble compounds. When treated with boiling dilute hydrochloric acid, the substance reduces the cupro-potassic liquor, while, with nitro-sulphuric acid, pachymose forms a gun-cotton-like substance. The formula of pachymose is $C_{30}H_{48}O_{12}$.

New Vanadiferous Silico-Aluminate of Manganese found at Salm-Chateau, Belgium.—F. Pisani.—The mineralogical description of this mineral is given at length. The sp. gr. of the substance is 3'577; it fuses readily in the blowpipe-flame, forming a black-coloured enamel. Its per cental composition is—Silica, 28'7; alumina, 28'36; peroxide of iron, 2'94; protoxide of manganese, 26'40; lime, 4'30; magnesia, 4'32; oxide of copper, 1'30; vanadic acid, 1'80; loss by ignition, 0'98; total, 99'10. The composition of this mineral, which is to be named Dewalquite, in honour of the eminent Belgian

mineralogist, Dr. Dewalque, resembles that of masonite, by supposing the iron therein contained to be replaced by manganese.

Le Moniteur Scientifique Quesneville, No. 372, December, 1872.

This number contains the following original memoirs relating to chemistry and collateral subjects:—

Platinum Coinage.—A. Jouglot.—In the introduction to this paper, the author discusses the question whether aluminium might be used as a substitute for bronze or copper coinage. His opinion is that the metal is not a suitable material for this purpose; but if there are invented cheaper methods for the production of aluminium, some of its alloys might be suitably used for coinage. Next, we have the enumeration of the properties of metals in general, so as to render them suitable for coinage. These properties, partly inherent to the metal itself, partly due to its intrinsic value (comparative scarcity), are all possessed in a high degree by platinum, which has been in use as a coin in Russia, but was demonetised by the imperial ukase of June 22, 1845, the reason being that at and before that period the proper methods of working and refining platinum were not well understood. In this respect, however, the researches of Drs. H. Sainte-Claire Deville and Debray, and Messrs. Johnson and Matthey, have made such changes, that there would now be no difficulty in the working of platinum into coins, and, unlike gold and silver, it would be proof against forgery, on account of its high specific gravity. So far back as 1799, experiments were made at the French Mint, at Paris, for the purpose of converting platinum into coins, and Duvivier produced at that period some beautiful specimens of platinum medals. This metal is still largely used for the same purpose in France. The author enters into exhaustive details on the alloys of platinum which might be used as material for coinage, and also gives some statistics on the annual production of platinum in different countries, observing that Dr. Pettenkofer's researches prove that platinum is more generally dispersed than is commonly believed.

Estimation of the Total Quantity of Phosphoric Acid present in a Soil.—E. Grandea.—The author first thoroughly dries a fair average sample of the soil, and next passes it through a fine sieve, thus eliminating pebbles. 100 grms. of the powder are then taken, and acted upon by pure nitric acid, aided by heat kept up for several hours. The acid solution is decanted, or, if necessary, filtered, and the insoluble residue well washed with distilled water, and the filtrate made up to 500 c.c. Into 100 c.c. thereof an excess of a solution of molybdate of ammonia is poured, and the precipitate of phosphomolybdate collected on a filter, well washed, and next dissolved in strong ammonia. The solution thus obtained, which should be clear and colourless, is used for estimating the phosphoric acid in ammoniomagnesian phosphate. Generally, the author makes a second estimation with another 100 c.c. of the original fluid, and finds that the difference in the two assays does not exceed 0.0005 grm. of phosphoric acid.

Although not belonging to chemistry, we call attention to the following essay:—

Transmission of Cholera by Ships, and on the Organisation of Quarantine.—Dr. M. Pettenkofer.

Bibliography.—Under this heading, we quote the title of the following work:—"Traité des Dérivés de la Houille Applicables à la Production des Matières Colorantes," par MM. Girard et G. de Laire; 1 vol., grand 8vo., de 650 pp., avec 12 planches. G. Masson, Paris; price 16 francs. This important work is divided into the following chapters:—Formation of tar; chlorated derivatives of the hydrocarbons; sulpho-derivatives of the aromatic carburets (*carbures aromatiques*); nitrated derivatives of the aromatic carburets; the coal-tar alkaloids; secondary and tertiary monamines; aromatic diamines; phenolen-diamine and isomers thereof; triamines; industrial applications; industrial manufacture of the coal-tar colours. The plates of this work, exhibiting apparatus and machinery, are drawn and engraved to scale.

Les Mondes, December 5, 1872.

Reorganisation of the Observatories in France.—By a decree of the President of the Republic, a committee of astronomers, mathematicians, and other *savants* has been appointed for the purpose of preparing a Bill to be presented to the Legislative Assembly, with the view of re-organising the existing observatories.

Oxyhydric Illumination.—Rev. Abbé Moigno.—The author reviews, in this paper, the official Report of F. Le Blanc, already briefly referred to in our columns (see *CHEMICAL NEWS*, vol. xxvii., p. 625), and points out that many of the conclusions arrived at by that gentleman are contradicted by the practical experience obtained at Brussels, Vienna, New York, and other large cities, and that the researches of Dr. Schilling, one of the most eminent scientific managers of gas-works, are also completely at variance with the views of Le Blanc.

November Meteors.—M. André and the Rev. Father Dutirou, S.J.—The authors communicate, from different localities of France (*viz.*, the former from Crépoul, the latter from Montauban), that during the night of November 27th last there was witnessed what might almost be termed complete showers of meteors. The weather was calm, sky clear, and the temperature moderately high for the season.

White Gunpowder.—L'Abbé Fortin.—It appears that, some three years back, the author invented a compound (the constituents are not mentioned) which, according to experiments made by competent artillerymen and scientific men, possesses advantages over ordinary gunpowder, gun-cotton, prussiate powder, picrate of potassa

powder, &c., in its mode of preparation, its freedom from danger by storage, as well as its not exploding by concussion, and the cheapness of its constituent materials, while its ballistic force is five times greater than that of the best ordinary gunpowder. The author also states that he can alter the mixture to any desired degree of strength and inflammability.

Thermoscopic Barometer.—A. Guioet.—The exhaustive description, elucidated by algebraical formulæ, of an ingeniously-contrived instrument, invented by the author, who received for it the silver medal of the Société d'Encouragement pour l'Industrie Nationale, and also a sum of money. It appears that the instrument has been found to give really correct indications, but hitherto it has not been sufficiently noticed out of Paris, where it is sold for 12 francs. The excellent editor of *Les Mondes* mentions incidentally that it has been tried with success in coal-pits as an indicator of the approach of fire-damp explosions, due to decrease of atmospheric pressure.

Journal für Praktische Chemie, Nos. 14 and 15 (double number), 1872.

Some Derivatives of Mucic Acid.—M. Kattnitz.—The end of this essay; this portion contains the following sections:—Behaviour of mucate of aniline when submitted to dry distillation; phenylpyrrol—

phenyl-pyrrol-mercurio-chloride—

mucate of toluidine, $\text{C}_6\text{H}_4\text{O}_6(\text{C}_6\text{H}_4\text{N})_2$; mucate of toluidine—

behaviour of mucate of toluidine when submitted to dry distillation.

Preparation and Properties of Protochloride of Gold (Gold-chlorür).—G. Leuchs.—After briefly referring to the modes of preparation and description of properties of this compound, as quoted in various works treating on chemistry, the author records at length the results of his experience in its preparation. It is best obtained by gently heating the perchloride of gold to from 180° to 200°, care being taken to stir the saline mass, which constantly evolves chlorine. The pure protochloride exhibits a yellow colour; this compound is decomposed by water and moist air, the result being the formation of metallic gold and perchloride of gold.

Detection of Water in Essential Oils.—G. Leuchs.—When, to the oils mentioned, a large quantity of petroleum ether (benzoline) is added, the water, if any is present, becomes apparent in the shape of drops.

Fortuitous Formation of Rosolate of Lime.—G. Leuchs.—On pulling down a roof covered with tarred felt, it was found that the layer of lime placed below it had in some parts become converted into rosolate of lime.

Products of the Action of Sodium upon a Mixture of Phosgen Ether and Iodide of Ethyl.—A. Geuther.—Notwithstanding the intrinsic value of this essay, its contents are not suited for abstraction, an observation also applying to the following memoir:—

Molecular and Usual Colours of the Metals, more particularly Gold, and on the Blue-Coloured Combination of Sulphur and Sulphuric Acid.—W. Stein.

Immediate Constituents of Bone-Ash.—Dr. C. Aeby.—This paper treats on a peculiar decomposition which the inorganic matter of bones undergo while being converted into bone-ash, and which is due to the loss of water of crystallisation of the phosphate of lime, and the action of the lime rendered caustic (from carbonate) upon the orthophosphate of lime.

Researches on Green Stones.—T. Petersen.—This mineralogico-chemical monograph is divided into the following sections:—Introduction and general review; the felspar theory; oligoclase from the diorite at Hof; oligoclase from the gneiss at Aschaltenburg; oligoclase from diabase; on the main constituents of massive rocks; felspar, augite, and hornblende; chlorite; magnetic and titanite iron; apatite; formation of serpentine; green stones as the matrix of many useful minerals and ores; method of chemical investigation; the diabases; general characteristics; fine-grained diabase from the Oederbach road, near Weilburg (Nassau-Prussia); coarse-grained diabase from the Lahn tunnel, a tunnel constructed for widening and canalising the river Lahn, at Weilburg; porphyroide diabase from Grävenek, near Weilburg; coarse-grained diabase from Tringenstein. This monograph, which is to be continued, is elucidated by a large number of results of analysis and complex formulæ. The rocks here alluded to also occur largely in some parts of Scotland, and are excellent as building-stone. Taymouth Castle is built of green stone, *chlorit-schiefer*.

Gazzetta Chimica Italiana, No. 7, 1872.

New Species of Calculi Urinarii from Cattle—Lithurate of Magnesia.—Dr. G. Roster.—The author relates at length under what conditions these urinary stones were emitted by the cattle, and describes the physical appearance, size, and weight of these stones, which he found to consist of lithurate of magnesia, $\text{C}_{10}\text{H}_{16}\text{N}_4\text{MgO}_4$. The lithuric acid is a snow-white crystalline substance, soluble in water and in alcohol; fusion-point, 204.5°; the small quantity of the acid obtained did not admit of establishing its chemical formula with

certainly, but it would appear that any of the following formulæ apply to this body:— $C_{10}H_{10}N_2O_{17}$; $C_{20}H_{20}N_4O_{18}$; $C_{18}H_{18}N_4O_{16}$.

Composition of Two Different Varieties of Sorghum Seeds.—Prof. A. Cossa.—The author has investigated the seeds of the sugar-yielding Sorghum and of the variety which is not sweet; the average weight of the former seed is 0.243 grm., that of the latter 0.284 grm. The composition of the sweet Sorghum seed, in 100 parts, is—Water, 14.19; organic matter, 82.84; ash, 2.97. Nitrogen, 1.571; fatty matter, 3.32. The seed which is not sweet contains, in 100 parts—Water, 13.21; organic matter, 84.84; ash, 1.95. Nitrogen, 1.484; fatty matter, 3.13. Husks of the sweet Sorghum seed contain, in 100 parts—Water, 12.04; organic matter, 81.87; ash, 5.19, of which 58.9 per cent is silica. The husks of that which is not sweet contain, in 100 parts—Water, 12.08; organic matter, 83.12; ash, 4.80, of which 67.94 per cent is silica.

Preparation of Caustic Potassa and Caustic Soda.—E. Poliaci.—The author discusses Dr. Wöhler's method (the reaction of copper at red heat upon the nitrates of the alkalis), and next a method invented by him of heating an intimate mixture of 2 to 3 parts of iron-filings with 1 part of nitrate of potassa, which mixture is heated to redness in an iron retort or crucible; the reaction which takes place is exhibited by the following formula:— $6KNO_3 + 10Fe = 3K_2O + 5Fe_2O_3 + 6N$.

Means of Ascertaining the Nature of the Dyes Applied to Woven Fabrics.—L. Gabba.—An essay of intrinsic value, but not suited for abstraction.

Chemical Composition of the Ash of the Leaves and of the Fruit of Lemons.—Prof. A. Cossa.—This lengthy essay contains, in the shape of a large number of tables, the results of a series of analyses of the ash of the leaves, fruit, and seeds of various kinds of lemons, and also of the soil on which the trees producing the same are grown; the contents of this essay are, however, mainly of local interest; these observations equally bear upon the following memoir:—

Chemical Researches on the Ripening of Grapes.—Prof. A. Cossa.

Annales de Chimie et de Physique, December, 1872.

This number contains the following original papers and memoirs:—

Researches on Nitro-Toluen.—Dr. Rosenstiel.—This exhaustive monograph is divided into the following sections:—Introduction, containing a review of the labours of several savants on this subject; immediate analysis of nitro-toluen; origin of the isomerism of the two nitro-toluen; is toluen a mixture of two isomeric carburets (*carbures*) on the simultaneous formation of the isomeric nitro-toluen in definite proportion? comparative study of the isomeric nitro-toluen; nitro-toluen- α (para-nitro-toluen of Beilstein and Kuhlberg); binitro-toluen- α (meta-para-binitro-toluen of Beilstein and Kuhlberg); nitro-toluen- β (meta-nitro-toluen of Beilstein and Kuhlberg).

Propagation of the Instantaneous Current of the Leyden Jar.—C. M. Guillemin.—Illustrated with woodcuts.

Light Emitted by Phosphorescent Uranium Compounds.—E. Becquerel.—This essay is the enlarged paper read by the author in the Academy of Sciences (see *CHEMICAL NEWS*, vol. xxvi., p. 82).

La Revue Scientifique de la France et de l'Etranger,
November 30, 1872.

This number contains the following original memoir collaterally relating to chemistry:—

Evolution of Organic Matter by the Processes of Living Organisms.—Dr. Wurtz.—The first portion of a series of papers on chemical biology.

December 7, 1872.

This number contains, in addition to a letter from the Minister of Public Instruction concerning the opening of the New Medical Faculty at Nancy, and the *éloge historique* on Isidore Geoffroy Saint-Hilaire, by Dr. J. Dumas, the following original essays relating to chemistry:—

The Hydrates of the Monobasic Fatty Acids.—E. Grimaux.—Not suited for abstraction.

Chemical Studies on Vegetation.—J. Raulin.—The results of the author's researches on the growth and development of the *Aspergillus niger*, and on the various conditions which promote, retard, or entirely prevent the formation of this microscopic cryptogamic plant.

Some curious statistics concerning the average duration of life of the Academicians are recorded in a paper written by M. Potiquet.

Bulletin de la Société Chimique de Paris, November 15, 1872.

This number contains no original papers.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale,
No. 240, December, 1872.

This number contains the following original paper relating to physical science:—

Report on, and Theory of, Bourbouse Balance Galvanometers.—M. De Lissajous.—This essay is illustrated by engravings, and contains the minute description of an ingeniously-contrived physical instrument of great value.

This number contains the exhaustive programme of the prize essays proposed to be answered by this society for the years 1873 to 1878 inclusive.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents,
54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

2672. E. Withy and W. Gibson, West Hartlepool, Durham, "Improvements in puddling furnaces, and in preparing iron for being operated upon therein and charging, such improvements in preparing for and charging being applicable in connection with cupolas, vibratory and refinery furnaces."—Petition recorded September 9, 1872.

3382. E. A. Cowper, Great George Street, Westminster, "Improvements in separating the fibres of materials producing paper pulp, and apparatus therefor."—Petition recorded November 13, 1872.

3412. G. Alsing, Preston, Lancashire, "Certain improvements in the treatment of night-soil and other refuse matter."—Petition recorded November 15, 1872.

3421. T. Bagley, Birmingham, "A new or improved varnish."—Petition recorded November 16, 1872.

3445. R. Hornby, Marchmont Street, Middlesex, "Improvements in treating fatty materials in combination with various kinds of pitch, alkalies, and oil, also in the treatment of animal, vegetable, and mineral oils for lubricating purposes."

3446. C. D. J. Seitz, Edinburgh, N.B., "An improved apparatus for, and method of, treating wood and other similar substances for the manufacture of half-stuff and paper."

3451. C. L. Siciemowski, Balham, Surrey, "Improvements in the preparation of photographic tracing-paper, and in the fluid employed in connection with the same."—Petitions recorded November 19, 1872.

3470. W. G. Brunner, Glasgow, N.B., "An improved process for annealing and cleansing the surfaces of iron or other metals."—A communication from Messrs. Schulz and Heyl, Berlin.—Petition recorded November 20, 1872.

INVENTION PROTECTED FOR SIX MONTHS BY THE DEPOSIT OF A COMPLETE SPECIFICATION.

3502. T. A. Howland and C. G. McKnight, M.D., Providence, Rhode Island, U.S.A., "Improvements in the manufacture of gas, and in apparatus therefor."—Petition recorded November 22, 1872.

NOTICES TO PROCEED.

2137. J. Dale, Manchester, "Improvements in the manufacture of oxalates of soda and potash."—Petition recorded July 17, 1872.

2262. T. R. Crampton, Great George Street, Westminster, "Improvements in the manufacture of gas and fuel, and in apparatus to be used for this purpose."—Petition recorded July 29, 1872.

2276. W. B. G. Bennett, Nichols Square, Hackney Road, and J. C. Watt, Lancaster Road, Notting Hill, Middlesex, "Improvements in the preparation of asphalt, and in the application thereof to the construction of roads and footpaths and other purposes."

2286. A. Browne, Gracechurch Street, London, "Improvements and modifications in the treatment of phosphate in general, and in the production and purification of phosphoric acid and its combinations."—A communication from H. Storck, E. Hentsch, A. Hentsch, A. Lutscher, and F. Grininger, Paris, France.—Petitions recorded July 30, 1872.

2476. A. Deiss, Plaistow, Essex, "A new or improved process of percolation, for the purpose of extracting fatty, resinous, and similar matters."—Petition recorded August 20, 1872.

3103. A. Allison, Bayswater, Middlesex, "Improved means of preserving and curing raw meat, in packing the same, and in apparatus employed therewith."—Petition recorded October 25, 1872.

3192. E. P. H. Vaughan, F.C.S., Chancery Lane, Middlesex, "Improvements in the mode of, and apparatus for, generating gas for lighting and heating purposes."—A communication from E. A. Dubois, Paris.—Petition recorded October 28, 1872.

3273. J. B. Spence, Manchester, "Improvements in obtaining anthracene, and in apparatus connected therewith."—A communication from J. C. F. Cheever, New York, U.S.A.—Petition recorded November 4, 1872.

3292. E. J. W. Parnacott, Leeds, "Improvements in artificial fuel, part of which improvements having reference to the means or apparatus employed in the manufacture of the same."—Petition recorded November 6, 1872.

3309. H. Deacon, Widnes, Lancashire, "Improvements in the manufacture of bleaching-liquor."—Petition recorded November 7, 1872.

PATENTS SEALED.

1616. J. H. Dennis, Liverpool, "Improvements in the treatment of copper precipitate and in the utilisation of impurities contained therein."—Dated May 28, 1872.

1634. L. G. Lysons, Gloucester, "Improvements in the manufacture or composition of paints or substances for covering or coating various surfaces."—Dated May 30, 1872.

1690. W. Riddell, Bishopsgate Street, London, "Improvements in the manufacture of paper pulp from vegetable fibres and in apparatus therefor, which apparatus is also designed to be employed in making chloride of lime for bleaching pulp, and in other similar processes."—Dated June 4, 1872.

2506. E. A. Cook, Viewville House, Midlothian, N.B., "Improvements in treating animal charcoal."—Dated August 23, 1872.

2843. F. Walton, Staines, Middlesex, "Improvements in oxidising oil, and in machinery to be employed for that purpose."—Dated September 26, 1872.

2950. T. Greener, Darlington, and W. Ellis, Gateshead, Durham, "Improvements in the manufacture of iron, and in the production of

'fetting' for improving the quality and yield of iron in the process of reduction."—Dated October 7, 1872.

2964. H. Larkin, Theydon Gernon, Essex, A. Leighton, Liverpool, and W. White, Hampstead, Middlesex, "Improvements in the production of iron and steel."—Dated October 8, 1872.

FOREIGN PATENTS.

BELGIUM.

31372. H. D. Poizot and A. Lagrelle, "Double extraction of beet-juice."
31374. L. and J. Jacobi, "An alloy which is proof against atmospheric action."
31391. J. B. Wattiaux, "New economical fuel."
31393. B. Todd, "Improvements in the treatment of gases and fumes."
31397. E. A. Dubois, "Improvements in the manufacture of lighting-gas, and in apparatus belonging thereto."
31400. F. Ransome, "Obtaining artificial stone."
31403. J. Palliser, V. Grumel, and A. Klopsk, "Decolouring and bleaching textile substances."
31407. C. de Sainte-Marie, "Preparing skins."
31408. D. Urquhart, "Improvements in preserving animal and vegetable substances."

UNITED STATES OF AMERICA.

132154. R. Guenther, "Washing compound."
132204. E. Fabra, "Medical compound for the cure of cholera in hogs, &c."
132333. S. M. Barnes, "Medical compound or anti-dyspeptic bitters."
132242. C. G. Bruce and M. J. Stein, "Process and apparatus for rendering and drying animal matter."
132243. C. G. Bruce and M. J. Stein, "Process and apparatus for treating and drying animal matter."
132264. H. H. Eames and C. J. Eames, "Treating ammoniacal liquor of gas-works, &c."
132265. H. H. Eames and C. J. Eames, "Manufacture of illuminating gas from hydrocarbons."
132266. H. H. Eames and C. J. Eames, "Vaporising hydrocarbons for heating, &c."
132269. W. Farris, "Tanning compound."
132272. F. G. Ford, "Preserving tomatoes."
132275. R. A. Gettings, "Medical compound."
132296. H. Lerner and E. C. Harpold, "Apparatus for the manufacture of bromine."
132324. L. H. Rogers, "Carbonised paper."
132331. L. Stevens, "Furnace for treating ores."

MEETINGS FOR THE WEEK.

- MONDAY, Dec. 16th.—Medical, 8.
Society of Arts, 8. Dr. C. Meymott Tidy. Cantor Lectures.
TUESDAY, 17th.—London Institution, 4.
Civil Engineers, 8. Anniversary.
Anthropological, 8.
WEDNESDAY, 18th.—Society of Arts, 8.
Geological, 8.
THURSDAY, 19th.—Zoological, 4.
Royal, 8.30.
Chemical, 8. E. Ludwig Mayor and C. R. A. Wright, "On the Polymerides of Morphine and their Derivatives." E. Nicholson, on "Analysis of Water of River Mahanuddy." Dr. H. E. Armstrong, "Communications from the Laboratory of the London Institution." J. L. Davies, "On the Formation of Crystallised Copper Sulphide, &c."
Philosophical Club, 6.

TO CORRESPONDENTS.

*. Vol. XXV. of the CHEMICAL NEWS, containing a copious index, is now ready, price 12s. 4d., by post, 12s., handsomely bound in cloth, gold lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 3s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxvi. commenced on July 5th, and will be complete in twenty-six numbers. READING CASES, price 1s. 6d. each, post free, may also be obtained at the Office.

W. Pakeman.—(1) Gentile's "Lehrbuch der Farbenfabrikation." (2) For practical purposes it is insoluble.

A Reader.—You will find the information in Brande's "Dictionary of Science, Literature, and Art," vol. iii. p. 313. Rottenstone is a peculiar kind of tripoli; you will find further information in Dana's "Mineralogy," p. 199. Both works may be consulted at the Library of the Commissioners of Patents.

Chemical Technology, or Chemistry in its

Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

THE LABORATORY will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

THE CLASSES will meet as usual.

THE CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

THE LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

THE MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

THE BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

THE CHEMICAL NEWS.

VOL. XXVI. No. 682.

ON

SUPERPHOSPHATES—THEIR ADULTERATIONS AND VALUATION.

By J. EMERSON REYNOLDS, M.R.C.P.,
Professor of Analytical Chemistry to the Royal Dublin Society,
Keeper of the Minerals, &c.,

HOWEVER much we may lament the existence of fraudulent dealing on moral grounds, it appears to me a study of high interest to follow this "trail of the serpent" amongst the things around us, to measure its effect upon the general welfare, and to devise means for its detection and suppression. In order to pursue such an inquiry with advantage, we must select a particular class of fraud; and the class to which I invite your attention this evening is that so frequently the subject of investigation by the analytical chemist—viz., the adulteration of articles of commerce. But I may further restrict the few remarks I have to make to a special order of adulteration which materially affects the agricultural community. The frauds to which I refer are those connected with artificial manures; but more particularly with the very important group of fertilisers included under the term "superphosphates."

We have had the opportunity of watching, for many years past, the steady development of a great trade in artificial manures, and the corresponding outcrop of devices by which dishonest traders have imposed on the farmer—with the result of diminishing his produce, and thus indirectly affecting the community at large.

To the agriculturist as to the manufacturer, the value of a superphosphate is directly proportional to the amount of soluble phosphate, insoluble phosphate, alkaline salt, and ammonia, either ready-formed or latent, that it contains. A very few seasons since, it was by no means uncommon to meet with superphosphate sold at a good price, and containing no soluble phosphate, and but a small proportion of other valuable substances—clay, road-stuff, gypsum, or waste products of various kinds from chemical works being used up in preparing the very feeble fertiliser. The same materials, of little value, were still more frequently used for diluting the genuine manure, and this practice is far from being uncommon at present.

I need not stop to consider in any detail the effect of this dishonest dealing on the farmer—his wasted means, unrequited labour, and consequent disappointment. To do more than refer to these misfortunes, and to the consequent national loss, would be to repeat an oft told tale.

The adulterators of superphosphate, bold though they were at first, soon received a check, for agricultural societies employed chemists in the detection of the frauds, with the result of obliging the greater cheats either to rest satisfied with the profits derivable from small adulterations, or to transfer their attentions to guanos or other substances that could be rather more safely tampered with.

Speaking now from my experience as chemist to this Society, I am justified in stating that gross adulterations of superphosphate are now rarely practised—probably not because the dishonest dealer has lost the desire for large profits, but for the sufficient reason that the risk of detection is now too great. He has, therefore, fallen back upon the more subtle plan of mixing with a manure a quantity of some nearly worthless substance that it already con-

tains as a natural constituent. The addition of gypsum to a superphosphate is an adulteration of this kind, for all these manures contain gypsum as a necessary product of the action of oil of vitriol on phosphate of lime, whether the latter is derived from bones, coprolites, or other similar mineral phosphates. When this addition of extraneous gypsum falls within certain limits, it is difficult to prove the adulteration, as manures of the same kind, and honestly prepared, are known to vary somewhat in composition. Now, under these circumstances it will be asked, What control have we over this more refined kind of adulteration? The answer to this ought to be, that a complete system of chemical valuation is employed by means of which any sensible reduction from a common standard is at once detected. But such an answer cannot as yet be truly given. Manures of the class referred to certainly have money values attached to them after analysis made on behalf of the purchaser or the vendor; but a very few examples will suffice to show how little importance is to be attached to such estimates. Thus, we find a manure selling at £6 per ton valued at £8 15s.; another, whose selling price is £6 5s., valued at £9 8s.; others, sold at £6 10s., £6 6s., and £7, appraised by one chemist at £7, £8, and £8 10s., respectively, and by another at £6 18s., £7, and £7 2s., though the two sets of analyses fairly agreed and were made about the same time. These discrepancies are accounted for to a considerable extent by supposing that one chemist attaches much more importance to certain constituents than another does; one values in the interest of the vendor, the other in that of the purchaser, and all the estimates are wide of the truth. Valuation of this kind, however, is probably useful for purposes of comparison when a particular set of samples are under examination; but, for general use, the system is simply misleading, and unable, in its present guise, to afford the information we require in dealing with doubtful cases. Hence, about three years ago, I ceased to assign money values to manures, unless where specially requested to do so on receiving a sample for analysis. I understand that Dr. Vöelcker, the distinguished chemist to the Royal Agricultural Society of England, now declines to attach a money value to a sample of manure under any circumstances.

Nevertheless, a satisfactory system of valuation ought to be constructed, as it is capable of rendering great service. I venture to think that no insuperable difficulties lie in the way, and my chief object is to lay before you the details of a plan for estimating relative values of superphosphates which appears to be fair alike to vendor and purchaser. If I succeed in proving to you, in the first place, that we may precisely fix the relative commercial values of the constituents of a superphosphate, and secondly, that we can take a standard to which reference can be made, it will be easy to complete the work and to show how the data may be utilised.

In dealing with the first branch of this question, it is well to explain at the outset the method of valuation at present employed. A certain money value per ton is assigned to each important constituent of a manure, thus: Ammonia, at £95 per ton; soluble phosphate, £30; insoluble phosphate, £11; alkaline salts, £3; organic matter, £1; gypsum, £1. A sample is analysed, and the percentage statement is held to indicate the composition of 100 tons. The number of tons of each body present is then multiplied by its price per ton, the various amounts then added together, and the estimated value of 100 tons obtained.

Having indicated the system at present in use, we now have to fix the relative values of the important constituents, by consulting dealers in the several raw materials as to their cost, and manufacturers of manure as to the expense attending the necessary treatment, excluding charges which do not affect the relative values. I have to acknowledge here the promptitude and courtesy with which my inquiries have almost invariably been met by many merchants, agents, and manufacturers. With-

out giving details of outlay, with which I have been kindly furnished in confidence from several quarters, I may now state the table of equivalent numbers that I have been thus enabled to construct, and these represent the mean of the several values at the present time. We may eliminate the organic matter that appears in an analysis from our list, since I give the equivalent of its latent ammonia, and gypsum, also because the equivalent of biphosphate includes that of the corresponding sulphuric acid of the gypsum. The table is therefore limited to the following six bodies, and these are referred to ammonia as unity:—

Ammonia, ready formed ..	1'0
Ammonia, latent	2'2
Biphosphate	4'0
Bone phosphate	8'0
Mineral phosphate	13'0
*Alkaline salts	22'5

This table somewhat resembles that of equivalents of the elements used in chemistry; that is to say, the numbers are strictly proportional to one another, and indicate the replacing values of the different bodies to the manufacturer.

The table also fairly represents the average relative values of the several substances to the farmer. Now, though the *average* agricultural values are not subject to fluctuation, the numbers in the above table require slight corrections to be applied to them from time to time, owing to variations in the *relative* cost of materials. Where any change of the kind is necessary, the correction should be applied prior to the commencement of each season, in order that all manures sold during a particular period should be fairly judged in the same way.

We have therefore substituted for money values a series of proportional numbers that can be used with great advantage, and have thus made the first step toward the solution of the proposed problem. As an example of the mode of using the figures, I may give the following analy-

sis of a fair mineral superphosphate offered for sale at £6 per ton:—

100 parts contained—

Water	12'85
*Organic and volatile matter ..	22'65
Biphosphate	16'99 ÷ 4'0 = 424'2
Neutral phosphate (mineral) ..	12'25 ÷ 13'0 = 94'2
Alkaline salts	1'50 ÷ 22'5 = 6'6
Sulphate of lime	29'06
Sand, &c.	4'70

100'00

*Ammonia 0'40 ÷ 1'0 = 40'0

565'0

In the above analysis, not made by me, the ammonia is not stated to be ready formed, nor is it shown to be latent. Under these circumstances, I consider it fair to the manufacturers to assume that it is immediately available, though it is highly improbable that all the nitrogen exists in the manure as ammonia. The percentages of the four valuable constituents have been divided by the corresponding equivalent numbers, and in the products the decimal points shifted two places to the right, in order to get convenient terms. The numbers have then been added together, and the product I call 565'0 on the R. D. S. scale of relative value. Instead of shifting the decimal points in the products, we may obviously do away with the decimal points in the analytical statement, and take the numbers given to represent parts in 10,000.

I now give a number of analyses of mineral and bone superphosphate made by different chemists. The samples are numbered, and the manufacturers' names suppressed, for obvious reasons. The *agents'* price to the farmer is given in each case, and the degree of the manure marked on the plan just described.

SUPERPHOSPHATES.

	MINERAL.					BONE.

Ammonia	1'00	0'13	0'12	0'12	0'30	3'62	1'49	2'53	1'40	1'10	1'20

Having pointed out the manner in which the table of equivalents can be used for the purpose of obtaining an accurate expression for the relative total values, we may discuss the data, and endeavour to deduce standards for the two classes of superphosphates.

Mineral Superphosphates.—With the exception of Nos. 1 and 2, all those manures whose analyses are given were sold at £6 10s. per ton to the farmer. By adding in each case one-thirteenth to the number found for Nos. 1 and 2 on the Royal Dublin Society's scale, we can consider them as if sold for £6 10s. per ton each—and therefore compare their number with those given for the remaining samples.

* The value of alkaline salts varies chiefly according to the proportion of potash salts present. In my opinion, it would be unfair to the manufacturer to assign to them a lower relative value than that given in the table.

In the following table these corrections have been made:—

Number.	Sold to Farmer at—	Degree on R.D.S. Scale.
1. ..	£6 10s. ..	612°.
2. ..	6 10s. ..	644°.
3. ..	6 10s. ..	630°.
4. ..	6 10s. ..	615°.
5. ..	6 10s. ..	520°.
6. ..	6 10s. ..	509°.

Dismissing Nos. 5 and 6 as being of inferior quality, we have four of these superphosphates, made by different manufacturers, sold at the same price, and approaching closely to each other in the number of degrees reached on the Royal Dublin Society scale. They are undoubtedly

useful fertilisers, and their mean number agrees with the mean afforded by my own analyses of corresponding samples. We are therefore in a position to fix our standard of value for a mineral superphosphate as follows:—*Samples marking 620° on the Royal Dublin Society scale above described, should not cost the farmer more than £6 10s. per ton.*

From the foregoing we at once deduce the simple and convenient statement, that a manure marking 600° R.D.S. degrees is worth just *six guineas* per ton.

A single example of the use that I make of this "Royal Dublin Society Standard Mineral Superphosphate" will suffice. Let us suppose that a farmer purchases a sample of mineral superphosphate at £6 10s. per ton, and that on the discussion of its analysis it affords the same number as No. 6, namely, 509° on the R. D. S. scale; we at once report the manure to be value for only £5 6s. 8d.

The money value obtained on the old plan and actually attached to No. 6 by the analyst was £6 7s. per ton. The latter estimation would, therefore, indicate to the purchaser at £6 10s. that he obtained fair value for his money, though really paying about £1 per ton too much. My system at once detects and measures this serious reduction in value.

Bone Superphosphates.—In these cases the equivalent number "8" of a bone phosphate (see table) has been used for dividing the insoluble phosphate; the number 13 being used for the same purpose in discussing the analyses of the mineral superphosphates. The superiority of undissolved bone phosphate over the mineral phosphate in the same condition being thus fully and fairly recognised, the degrees on the R. D. S. scale afforded by the bone manure of course have the same meaning as when deduced from the analysis of a mineral superphosphate. Our standard mineral superphosphate, therefore, measures the value of a bone manure. If, then, the former is only value for £6 10s. per ton, when it marks 620° on the R. D. S. scale, the bone manure is only value for £8 per ton when it reaches 763° on the same scale.

Having deduced our standard from the previous inquiry, we may now ascertain how far the result is confirmed on the discussion of the above given analyses of bone superphosphates.

We first have to raise the equivalent of No. 10 from 573° to 679°, being in the ratio of £6 15s. to £8, and then tabulate the numbers as before, thus:—

Number.	Sold to Farmer.	Degree on R.D.S. Scale.
7. . . .	£8 0 0	883°.
8. . . .	do.	537°.
9. . . .	do.	600°.
10. . . .	do.	679°.
11. . . .	do.	655°.
12. . . .	do.	811°.

Nos. 7 and 12 are derived from vendor's analyses, the rest from those of purchasers. No. 8 is so obviously a very inferior manure that we may dismiss it from consideration. Then, taking the average of the remaining five samples we get as the mean result on the R. D. S. scale 745°. We are therefore fully justified in adopting as a fair standard that which we have deduced from other considerations, namely, 763° on the Royal Dublin Society scale for a sample of bone superphosphate costing the farmer not more than £8 per ton.

Having, I hope, shown that the existing system of valuation of superphosphates may be replaced with advantage by another capable of yielding results of higher accuracy and practical value, and having fixed certain standards, by reference to which these artificial manures can be adjudicated upon with fairness alike to the vendor and the farmer; I ought to give notice that all superphosphates sent to the Royal Dublin Society for analysis must now be valued on the above plan.

In concluding this paper I may venture to express the opinion that much public advantage would accrue if the Royal Dublin Society offered some inducement to dealers

in superphosphates to compete, on the understanding that the best sample offered at a given price to the farmer should be used as a standard for reference during the season immediately following the competition. However until some such plan is adopted, I venture to think we may fairly rest content with the standards I have now endeavoured to fix.

ON THE PRODUCTION OF FURFURAL BY THE ACTION OF HIGH-PRESSURE STEAM UPON WOOD.

By GREVILLE WILLIAMS, F.R.S.

(Continued from p. 231.)

HAVING shown that furfural is formed when wood is heated with water to an elevated temperature and pressure, which result has since been confirmed by Mr. Hugo Müller,* I now proceed to give the method by which I found it to be produced by the action of high-pressure steam on the same substance.

The apparatus employed is shown in the engraving. A A is a bronze autoclave, made in one piece, and of great strength. Before being employed it was tested by means of a hydraulic pump, and was found to withstand a pressure of 500 lbs. to the inch without leakage. Before

using the instrument a ring of vulcanised india-rubber was placed between the autoclave and its cover, B B. The screw, C, which serves to keep down the cover, is forced home by means of a wrench applied at L. The arms, D D, serving to support the screw, are affixed to projections on the autoclave, by movable steel pins inserted at E E. A screw-tap, F, enables the product to be distilled over at the conclusion of the operation. The pressures are indicated by the gauge, G. A cylinder of perforated metal, H, is used to contain the substance to be experimented upon; which, in this case, was pine sawdust. The shelf, I, also perforated, prevents contact of the sawdust with the water, the level of the latter being shown at K K.

The water and the charge of sawdust having been introduced, the apparatus was immersed to about half its depth in an oil-bath, the temperature being carefully

regulated by means of a thermometer. The oil-bath was then heated until the gauge indicated a pressure of 100 lbs. to the inch; this pressure was maintained in some experiments for three, and in others for four hours, the average temperature of the oil-bath being about 198°C . The apparatus having been allowed to cool until the pressure had completely gone down, was then connected with a condensing arrangement. The screw, F, was then loosened, and heat was applied to the oil-bath until about three-fourths of the water present had distilled over. The distillate was strongly acid to test-paper, and smelt decidedly of furfural, mixed with an empyreumatic odour. On the addition of ammonia it acquired a yellow tint, and in a few hours deposited the characteristic crystals of furfuramide. The crude distillate, mixed with aniline and acetic or hydrochloric acid, instantly gave the magnificent crimson colouration indicative of furfural. To prove that the crystalline precipitate with ammonia was really furfuramide, I distilled it with a very small quantity of hydrochloric acid; the distillate immediately gave the crimson reaction with aniline. The crystals, treated with acetic acid and aniline, also reacted in the same manner.

From the scale upon which the operation was made, the quantity of furfural obtained was, however, necessarily small.

The arrangement of the apparatus used in this experiment renders it evident that if the furfural formed was due to the presence of organic acids, they must have acted in the state of vapour. The experiments I have as yet made seem, however, rather to indicate that the furfural and the acids are formed simultaneously.

Water alone, and steam alone, being therefore capable—at comparatively high temperatures and pressures—of causing the production of furfural from wood, I next proceeded to ascertain whether that substance would yield furfural when distilled with water at normal pressures. I therefore distilled 100 lbs. of sawdust with 100 gallons of water, in a still heated by a copper steam coil: 20 gallons were distilled over. These 20 gallons were put into a small copper still, and the first 10 gallons received. These in their turn were rectified again, and two received. In spite of the concentration which these liquors had undergone, I was unable to obtain furfuramide on digestion with ammonia, and, in fact, they only contained minute traces of furfural. The high temperature, and consequently pressure, are therefore necessary to the reaction, and this fact forbids the supposition that the furfural might have been formed during the final process of distillation from the autoclave.

Star Chemical Works, Brentford,
December, 1872.

ON THE HISTORY OF OZONE.*

By Professor ODLING, F.R.S.

Concluded from p. 283.

V.

It has just been remarked that in the action of the contracted gas on iodide of potassium solution, there is absorbed by the reagent, with equivalent liberation of iodine, a weight of oxygen corresponding to a volume equal to that of the original contraction; but very curiously, the absorption by the reagent of this weight of oxygen from the contracted gas was found by Messrs. Andrews and Tait not to produce any further contraction or alteration of its volume; or the weight of oxygen which acted on the iodide of potassium solution appeared to occupy no part of the volume of the contracted gas, its removal from the contracted gas by means of the reagent not affecting any alteration in that volume. Since this remarkable result was first announced by Messrs. Andrews

and Tait in 1860, it has been abundantly confirmed by von Babo and Claus, by Soret, and by Sir Benjamin Brodie—the modes of experimenting adopted in the original investigation of Andrews and Tait and in the three subsequent investigations, being all different from one another. And moreover, not only has the fact been established by the four several investigations with regard to iodide of potassium, but by one or other of the investigations with regard also to iodine, to mercurous salts, to ferrous salts, to arsenites, and to ferrocyanides. So that, when a given volume of ozonised oxygen is allowed to act upon these different oxidisable bodies, the oxidation effected by the ozone present in the gas is found to be unattended by any diminution in the volume of the gas. An interpretation of this singular result was put forward by the speaker soon after the publication of Messrs. Andrews and Tait's experiments, to the following effect:—Ozone being proved to be a condensed form of oxygen, it is clear that any volume of ozone will contain a greater weight of the matter of oxygen than is contained in the same volume of ordinary oxygen. And since in the action of ozone upon iodide of potassium, the volume of the reacting gas does not undergo any alteration, it is obvious that the oxidation effected must be effected by only so much of the matter of oxygen contained in the volume of ozone as is in excess of the matter of oxygen contained in the same volume of ordinary oxygen. This interpretation, so far as it went, was considered to be demanded by Messrs. Andrews and Tait's experiments, as the only satisfactory explanation of them. With regard to the weight of the matter of oxygen contained in a given volume of ozone, in excess of the weight of the matter of oxygen contained in the same volume of ordinary oxygen, no data whatever existed to show what this weight really is. But relying upon the fact that the weight of oxygen contained in a standard volume of free oxygen is composed of two simple weights of the matter of oxygen, it was conjectured that the weight of oxygen contained in a standard volume of ozone might not improbably be constituted by an introduction into the standard volume of ordinary oxygen of another simple weight of oxygen—equal volumes of ozone, free oxygen, and nitric oxide, for example, being expressible by the comparable formulæ O_3 , O_2 , and NO respectively. In accordance with this supposition, the action of ozonised gas upon iodide of potassium, &c., is explicable as follows:—The ozone which acts is decomposed into a weight of free oxygen equal in volume to the volume of the ozone, and into another weight of absorbed oxygen, assumed to be one-half of the former weight. The suggestion as to the standard volume of ozone being constituted thus of three simple weights of the matter of oxygen, was admittedly not a necessary deduction from the then known facts, which were indeed equally consistent with its being constituted of four, five, or six such weights; it was only the suggestion of the simplest possible constitution for ozone that was consistent with the facts.

A few years afterwards, in 1865-66, the probability of this being the real constitution of ozone was much strengthened by the results of some experiments conducted by Soret. Operating by a process very simple and ingenious, but scarcely calculated to afford precise results, Soret found that when electrolytically obtained ozonised oxygen was allowed to act upon oil of turpentine, the absorption of the ozone by the turpentine was attended by a diminution in the volume of the gas equal approximately to twice the initial contraction,—as inferred, of course, from the iodine-titre of the ozonised gas, or from its permanent expansion after exposure to a temporary heat. Supposing the final diminution effected by the turpentine to have been exactly twice the initial contraction, inferred from the iodine-titre, it is clear, that what the original gas would have suffered altogether a diminution of three volumes, the ozonised gas would have suffered a diminution of only two volumes. Or there would have been ultimately abstracted from the original uncontracted

* Read before the Royal Institution of Great Britain.

gas three volumes of the matter of oxygen, occupying in the contracted or ozonised gas, submitted to the action of the turpentine, only the bulk of two volumes. But as a mean result of Soret's first set of five experiments, the final diminution effected by the turpentine was 2.40 times the original contraction; while, as a mean result of his second set of seven experiments, the final diminution was 1.81 times the original contraction. Assuming, however, ozone to have the constitution expressed by the symbol O_3 , its specific gravity, and consequently its diffusion-velocity, would approximate closely to the specific gravity and diffusion-velocity of carbonic acid gas, CO_2 ; and in 1867, Soret, in corroboration of his previous absorption results, satisfied himself that the diffusion-velocity of ozone really does approximate very closely to that of carbonic acid.

VI.

During the last few years, the quantitative reactions of ozone have been made the subject of an elaborate study by Sir Benjamin Brodie, whose results constitute indeed "a body of exact information as to the chemical properties of ozone, through which it may be hoped that this important question will be finally removed from the domain of arbitrary speculation and brought within the precincts of science." In Brodie's experiments, a quantity of pure perfectly dry oxygen, after having been submitted to electrification by its passage through a modified form of Siemens's induction tube, carefully maintained at a low temperature, was collected in an oil of vitriol gas-holder, to the amount of four or five thousand c.c. From the store of ozonised gas thus collected, which was found to maintain its proportion of ozone without appreciable deterioration for some hours, portion after portion was allowed to pass into a pipette of about 250 c.c. capacity, by displacement of the oil of vitriol originally filling it; and successive equal volumes of the store of ozonised gas so measured off, were submitted one after another to the action of the same or of different reagents, by the passage of each pipetteful of gas through a small bulb-tube containing the reagent in solution. The gas, freed from all ozone by its passage through the reagent, was next received into a mercurial measuring cylinder, in which it was expanded to a definite volume; and then, by reading off the pressure at which it occupied this volume, its proper volume was ascertained. Finally the difference between the capacity of the pipette and the volume obtained in the mercurial cylinder showed the volume of the gas absorbed by the reagent,—the weight of this gas being determined directly or indirectly by titrations of the reagent. Of course, very many points of detail in the construction and use of the apparatus had to be attended to, in order to ensure trustworthy results; but, both in its principle and general working, the process is exceedingly simple. One essential novelty consists in the application of that very useful instrument, the pipette, to the purposes of gas analysis; and by its aid, results having a degree of accuracy far greater than those furnished by any previous method of ozone investigation, were found to be obtainable with both speed and facility.

Operating, then, with the apparatus just described, Brodie has succeeded in establishing three perfectly definite classes of ozone reactions,—the first of them including the instances previously made known by Andrews and Tait. In this first class of reactions, of which there are several distinct varieties, the absorption or decomposition of the ozone present in a mixture of ozone and oxygen, is unattended by any diminution in the volume of the gas; or a volume of ozone O_{2+x} , is resolved into an equal volume of free oxygen, and an indefinite weight of other oxygen, either absorbed or set free. This class of reactions accordingly does not afford any information as to the formula O_{2+x} , or, in other words, as to the relationship of the

In a second class of reactions, the absorption or decomposition of the ozone present in a mixture of ozone and oxygen is attended with a diminution in the volume of the gas, equal to half the volume that the weight of oxygen absorbed would occupy in the free state. In this class of reactions, then, one of but two occurrences must happen: either the ozone present in the mixture of gases is absorbed wholly without decomposition, in which case the density of ozone must be twice that of ordinary oxygen, and the formula O_{2+x} become O^* ; or the ozone present in the mixture is decomposed into half its volume of oxygen liberated, and into a quantity of oxygen, corresponding to its entire volume, absorbed; in which case the density of ozone must be one and a-half that of ordinary oxygen, and the formula O_{2+x} become O_1 .

Unit-Volumes.

$$\left. \begin{array}{l} O_{2+x} = n\bar{il} + 4O \\ 2(O_{2+x}) = O^* + 4O \end{array} \right\} \text{absorbed.}$$

In a third class of reactions, the absorption or decomposition of the ozone present in a mixture of ozone and oxygen is attended with a diminution in volume of the gas, equal to two-thirds the volume that the weight of oxygen absorbed would occupy in the free state; or the weight of the gas absorbed is to the weight of an equal volume of oxygen as 3 to 2. But consistently with this class of reactions, the density of ozone must necessarily be one and a-half times that of ordinary oxygen, and the formula O_{2+x} must become O^* .

Unit-Vols.

$$O_{2+x} = n\bar{il} + 3O.$$

This last and most important class of reactions, by which the formula of ozone as O^* is put beyond question, was established by a long series of experiments, made chiefly with a neutral or but slightly alkaline solution of hyposulphite of soda, and in a few cases with oil of turpentine. As a result, the ratio of the entire diminution in volume suffered by the original oxygen, to the diminution in volume of the electrified or contracted oxygen effected by the reagent, was found to be, as a mean of twenty-seven concordant experiments made with the hyposulphite, 3.02 to 2.02; and as a mean of eight concordant experiments made with the turpentine, also as 3.02 to 2.02. But neither with the hyposulphite nor with the turpentine could the weight of oxygen absorbed by the reagent be determined, otherwise than by a calculation from the alteration in volume of the gas. A direct determination, however, was effected in the case of a few experiments made with protochloride of tin, under conditions carefully considered and regulated so as to ensure a trustworthy result. And it was found, in these few experiments, that the weight of the matter of oxygen absorbed from the ozonised gas by the tin salt, was almost exactly three times the weight of the matter of oxygen absorbed from the same gas by iodide of potassium,—the volume occupied by the weight of oxygen absorbed by the tin salt being almost exactly twice the volume proper to the weight of oxygen absorbed by the iodide of potassium.

Independently of the importance attaching to the actual determination of the density of ozone, Sir B. Brodie's result has a further interest for chemists, which it would be difficult to exaggerate. The principal of the elementary bodies, known to chemists in the gaseous or vapourous state, are hydrogen, chlorine and its congeners, oxygen, sulphur, nitrogen, phosphorus, arsenic, mercury, and cadmium. Now it is a fact that the weight of phosphorus or arsenic contained in any volume of phosphorus or arsenic vapour is four times the weight of phosphorus or arsenic contained in the same volume of phosphoretted or arsenetted hydrogen, and of a host of other phosphoretted or arsenetted gases or vapours. It is also a fact that the weight of hydrogen, chlorine, oxygen, or nitrogen contained in any volume of each of these elementary gases is twice the weight of hydrogen, chlorine, oxygen,

$$O_{2+x} = O^* + xU \text{ absorbed.}$$

nitrogen contained in the same volume of a variety of hydrogenous, chlorinous, oxygenous, or nitrogenous compound gases. It is also a fact that the weight of mercury or cadmium contained in any volume of the vapour of either element is identical with the weight of the element contained in the same volume of the vapour of all its hitherto examined volatile compounds. But now a variety of oxygen is shown to exist, the weight of any given volume of which is three times the weight of oxygen contained in the same volume of the simplest of oxygenous compounds respectively, thus:—

Unit-Volumes.			
P ₄	O ₃	O ₂	Hg
PCl ₃	CO	NO	HgCl ₂

The question, then, naturally arises, how long will it be before another variety of oxygen is recognised, the weight of any given volume of which, like that of a given volume of phosphorus vapour, shall furnish the weight of the element contained in four such volumes of its several simplest compounds? And again, how long will it be before yet another variety of oxygen is recognised, the weight of any given volume of which, like that of any given volume of mercury vapour, shall furnish but the weight of the element contained in the same volume of its several simplest compounds? There is the strongest indirect reason for believing in the existence of such a unitary oxygen. For in its reactions, oxygen behaves as a sort of more active electro-negative counterpart of electro-positive mercury Hg; and like mercury, Hg, and unlike hydrogen, H₂, and chlorine, Cl₂, it enjoys the property of adding itself to a pre-formed unit of substance by an indivisible proportion.

PASSAGE OF HEAT RAYS THROUGH INCLINED DIATHERMANOUS PLATES.

(Concluded from p. 269).

IN the first part of Professor Knoblauch's paper, the influence of polarisation of heat rays is investigated, apart (as much as possible) from the absorbent nature of the plates. The latter influence falls now to be considered.

A series of experiments are detailed, in which glasses of various colours were employed, the number of plates and angle of incidence being varied several times for each. The more prominent results from this part of the enquiry are these:—

(1). Where parallel heat rays fall on parallel diathermanous plates (varying in number), and where, with perpendicular incidence, the quantity of heat transmitted through different numbers of plates, is, through a special arrangement made in each case, the same; then, on varying the angle for any one number of plates, the heat transmitted is less, and this in proportion as the substance is less diathermanous. This occurs also whether the heat rays are unpolarised, or polarised, in any plane. For the same angle of incidence and the same number of plates, the transmission, as indicated by the multiplier, was greatest with colourless glass, smaller with yellowish green, still smaller with blue (bright blue giving more than dark), and smallest with bluish green glass.

(2). When the incident heat is unpolarised (or polarised at 45°), then, through the partial polarisation which is produced on refraction in the plate (and the plane of which is at right angles to the plane of refraction), the decrease, due to absorption in the aforementioned case, is at first prevented more or less in proportion as the substance of the plate is more or less diathermanous; but a very much faster decrease of the heat appears after the angle of polarisation is passed. Thus, with colourless and yellowish green glass, the heat intensity continued constant till the angle of incidence, 55°; with the bright blue till 25°; whereas with dark blue and bluish green a decrease began at 15°, and this increased greatly after 55°.

(3). When the heat rays were perfectly polarised before entrance into the plate, and the planes of polarisation and of refraction coincided, then, with increasing incidence and number of plates, the transmission was diminished, but the diminution was greater than in the previous case, and also greater the less diathermanous the substance of the plates.

(4). On the other hand, when the original polarisation was such that the planes of refraction and polarisation crossed at right angles, then, till the angle of incidence exceeded the angle of polarisation, there was not only no decrease of the transmitted heat, but a positive increase, and this was the greater in proportion as the plates were more diathermanous. Sometimes the maximum transmission was reached before the angle of polarisation. When this angle was passed, the decrease which took place was always less than in the case of unpolarised rays. The increase of the plates favoured the increase now referred to, and this influence is more marked the more diathermanous the substance, till continued increase of the angle of incidence and number of plates produces decrease of transmitted heat.—*Pogg. Ann.*

THE QUANTITATIVE ESTIMATION OF MANGANESE IN SOILS AND IN THE ASH OF PLANTS.

By A. LECLERC.

THE ordinary gravimetric methods of estimating manganese in soils and in the ashes of plants are not sufficiently correct to yield good and reliable results, unless, indeed, a very large quantity of material is operated upon at the same time.

The method which I propose and expound in this paper is a volumetric one, which may be rapidly, yet accurately, performed. The plan consists in the conversion of nitrate of manganese into a permanganate, and the titration of the latter by means of a suitable solution. The conversion just mentioned is readily effected by the aid of red-lead, because the iron and aluminium, the only substances which could react upon the permanganate, are at the time of the conversion already peroxidised. The reaction alluded to will always succeed, provided there be no chlorine present in the substances employed.

Before detailing the quantitative operation, it is necessary to describe the practical details of the experiments. When a soil (arable or other) is to be operated upon by nitric acid, it is first necessary to destroy the organic matter it contains by igniting the soil to red heat. It is next boiled with nitric acid, care being taken not to evaporate the solution to dryness, since, owing to the fact that the nitrate of manganese is decomposed, at 142°, into MnO₂, which is insoluble in nitric acid, manganese might be lost. When the nitric acid appears to have taken up all the manganese, the liquid is filtered, and then diluted with water up to a given and determined bulk. A fraction of this fluid, viz., that in which the chlorine has been estimated by means of nitrate of silver, is next boiled in a porcelain capsule, and after boiling, some red-lead is added, care being taken to stir the fluid. The result is, that the fluid assumes a beautiful violet colour, due to permanganate of potassa, the colour being somewhat masked by that of the peroxide of lead, which is simultaneously formed and deposited in insoluble condition. The depth of the violet colouration depends upon the greater or less amount of manganese present. If it should happen that the red-lead be not acted upon, it is due to the liquor not being sufficiently acid, and consequently some more nitric acid will have to be added. The liquor is filtered, and the precipitate of lead having been precipitated, the filtrate is then through asbestos free from chlorine. The filtrate is then ready for titration, the filtrate containing a slight excess of

nitric acid, permanganate of potassa, nitrate of lead, salts of iron, alumina, magnesia, lime, soda, and potassa. Titration by means of the double sulphate of iron and ammonia is out of the question, because the formation of sulphate of lead would prevent the end of the reaction from being seen, and oxalic acid cannot be used, both on account of its giving rise to the formation of carbonate of lead, and because it requires a higher temperature. I therefore looked for another reducing agent which would allow me to observe correctly the change of the violet to another colour; the nitrate of protoxide of mercury I found to answer my purpose in this respect. This salt is rapidly converted into the nitrate of peroxide of mercury by the permanganate, and the end of the reaction is marked either by a yellowish green colouration, when much manganese is present, or by complete decolouration of the fluid if only a little of the metal is present. The solution of subnitrate of mercury does not form any precipitate, unless, indeed, too much manganese were present, but care should be taken that the liquid to be titrated is rather freely acid, because otherwise sesquioxide of manganese is thrown down. The solution of subnitrate of mercury is first titrated by means of permanganate.

Description of the Experiments.

Expt. 1.—50 grms. of soil are treated, as above indicated, with nitric acid, the liquid is filtered, and the filtrate diluted to 1000 c.c. Three titrations, made with 100 c.c. each, have, on an average, given the following results:—3.39 c.c. of subnitrate of mercury (1 c.c. thereof = to 1.121 m.grm. of Mn), corresponding to $1.121 \times 3.39 = 3.8102$ of manganese. 50 grms. of the same soil, to which have been first added 10 c.c. of a titrated solution of permanganate (this liquid containing 2.366 m.grm. of manganese to the c.c.) have been treated in the same way, and five titrations, made with 100 c.c. each, have given, on an average, 5.51 c.c. of subnitrate used, corresponding to $1.121 \times 5.51 = 6.1767$ m.grm. of manganese. According to these estimations, there would be an increase of $6.1767 - 3.8102 = 2.3665$ of manganese, corresponding to the quantity added, for 100 c.c., to the soil in the shape of permanganate. We have therefore—

Manganese found by analysis	2.3665 m.grm.
Manganese added.. ..	2.3660 "
Difference, an excess of	0.0005 "

Expt. 2.—5 grms. of ash have been treated in the same way as the soil. The filtrate having been diluted to 500 c.c., the titrations made with 50 c.c. give an average of 14 c.c. of subnitrate used, corresponding to—

$$1.121 \times 14 = 15.694 \text{ m.grm. of manganese.}$$

To 5 grms. of the ash have been added, after treatment with nitric acid, 5 c.c. of permanganate (5 at 1.1830 m.grm. Mn); the filtrate having been diluted to 500 c.c., the average of the titrations made with 50 c.c. shows that 15.055 c.c. of subnitrate of mercury have been used, corresponding to $1.121 \times 15.055 = 16.8766$ m.grm. of manganese. Accordingly there is an increase of manganese for $16.8766 - 15.694 = 1.1826$ m.grm. of manganese, a quantity corresponding, for 50 c.c., to that added to the ash, and we have therefore—

Manganese added.. ..	1.1830 m.grm.
Manganese found.. ..	1.1826 "

Difference, minus 0.0004 "

The author adds to this paper a very extensive tabulated form, showing the results of a series of experiments made with various soils of different geological formations, from which it appears that the method above-mentioned yields very accurate results. We do not here give this tabulated form, because the figures quoted relate particularly to French soil, but as instances we quote the following figures:—

	Mn ₂ O ₃ , per cent.
Alluvial soil (Toulouse)	0.078
Granite (Remiremont)	0.060
Chalk formation (Yonne)	0.276
Sandstone (Vosges) varies from 0.037 to 0.1860	
Ashes of plants—	
Oak	1.4880
Fir tree	4.5070
Lime tree	3.7440
Vine (stem)	0.1910
" (root)	0.1300
Grain—	
Wheat	0.0113
Rice	0.0010
Pulverised bones	0.0061
" coprolites	0.1460

The theory of the method above described is exhibited by the following formula—

The supposition of the precipitation of Mn_2O_3 has been verified by experiment. The precipitate, on being tested after titration, has been found to be sesquioxide of manganese.—*Comptes Rendus.*

MINERALOGY.

THE third lecture of the series, by W. W. Smyth, F.R.S., on Monday evening, November 25, was on "Silica, or Quartz and its Varieties."

The term crystal (from the Greek *crystallos*, ice) was first applied to crystal of quartz or rock crystal; which was regarded as a variety of ice. It belongs to a class of minerals characterised by having silica for their chief constituent, and of which it is the purest variety. Its crystals belong to the hexagonal system, quartz crystals usually assuming the form of a six-sided prism, terminated at both ends by a six-sided pyramid. The largest and most beautiful crystals are from Madagascar. The substance is extremely hard, and cannot be scratched by steel, and can only be worked by taking advantage of its brittleness. The substance used for "pebble spectacles" and "pebble lenses" is crystalline quartz, brought chiefly from Brazil; and is valuable for these purposes not only on account of its transparency, but especially on account of its coolness. A less crystalline variety is known as common quartz, and is exceedingly interesting as being in many cases the matrix in which gold is found in the mining districts. Some fine specimens of this auriferous quartz from California and Australia may be seen in the Geological Museum.

The lecturer exhibited a fine specimen of quartz to illustrate the phenomenon of pseudomorphism, which was full of casts of crystals of cubic and rhombohedral form, in the latter of which forms quartz is very seldom found crystallised, and never in the former. He explained their origin by supposing the quartz to have been deposited round crystals of some other materials (e.g., in veins) which have since been removed. Quartz is very frequently found filling up fissures in the rocks, or forming veins, and in some of these veins valuable mineral ores are found, for example, the tin ores of Cornwall. Galleries are driven in the rocks, and the whole of the material in the productive veins removed with the exception of bars at various levels, left as floors and to prevent the side walls from collapsing. Many serious accidents have occurred by the giving way of these masses, both in California and in our own country. If any circumstance has prevented the quartz from attaining its proper degree of coherence and hardness, or if any impurity is present (e.g., a thin layer of clay) to destroy its continuity, it is quite unsafe to work underneath these galleries.

Jasper is a variety of quartz of a red, brown, or greenish tint. Caerngorm is another variety which is obtained from the mountain of that name in Scotland. "Smoky quartz" is so named from its smoky appearance; and "rose quartz" from its tint, which is due to the presence of a metallic oxide. Amethyst likewise belongs to the quartz family of minerals, and has a beautiful purple tint. It owes its name to a strange fancy regarding it in olden time, namely that the wearer of it was preserved from inebriation. Under the term "agate" a large number of minerals are arranged, which agree in being made up of layers or bands of material, coloured more or less distinctly. They are often found wholly or partly filling up the hollows of certain cavernous substances, and appear to have been deposited from solution in water. If the layers are strongly contrasted, as black and white, the name onyx is given to it, and if in addition to these a reddish layer is present it is called sardonyx. Aventurine is a brownish mineral containing numerous little plates of mica, which act as so many spangles in reflecting the light.

Calcedony (of which certain stalactitic forms are known) carnelian and sard also belongs to this class. With respect to sard, the lecturer took occasion to call attention to those exceedingly beautiful "engraved gems," which he characterised as examples of the highest art-workmanship of antiquity which has come down to us. The beautiful polish which the substance is capable of taking, and its great durability, made it to be much valued by ancient lapidaries. And both these qualities rendered it and allied substances well fitted for cutting into signet rings, which in those times were objects of such common use.

In the form of sandstones quartz is in common use for building processes. It has been reduced to this form by the action of the waves and other agencies, and can be easily worked and split up into flagstones, &c.; sometimes sufficiently thin as to be used for roofing materials. Grit is a coarser form of a similar nature; and a coarser still is known as "plum-pudding stone."

An amorphous variety of quartz minerals, containing from 4 to 7 per cent of water, is termed opal. This is one of the most interesting varieties of the family, as showing the probable mode of their formation. It appears to have been deposited from water, and in some cases, as at Antigua in the West Indies, and in Hungary, trunks of trees and pieces of wood are found completely opalised. Noble, or precious opal, is found in Hungary very near to places where the mineralised wood occurs.

In Iceland and New Zealand, at the present day we see an example of siliceous matter being deposited from hot water. The orifices of the Icelandic geysers are surrounded by basins composed of this siliceous sinter, which is likewise deposited on materials placed in the water. The lecturer had a specimen of a stick thus silicified in the water of these springs. He had also an illustration of a very curious mode of rock formation by means of hot springs in North Island, New Zealand, which consists of a natural cascade formed entirely from the siliceous matter deposited from boiling springs. The various steps of the cascade were circular or basin shaped, and were all seen to be overflowing with water. In conclusion he said that probably these hot mineral springs had been the chief agency in filling up the veins in the rocks.

"Silicate Minerals and the Silicate Gems" was the subject of the fourth lecture of the course by W. W. Smyth, F.R.S., delivered at the Geological Museum on Monday evening, December 2nd.

Silicates are substances which contain a large amount of silica (a compound of silicon and oxygen), and of these there are numerous varieties. Some are hydrous, others anhydrous; to the latter class the lecturer proposed to confine his remarks. Gems are mineral substances having an agreeable tint of colour, a certain amount of transparency

and brilliancy, and especially a great degree of hardness, enabling them to retain their forms and features for ages; besides the above qualities, rarity is to a certain extent an element in their value. Beautiful substances, wanting more or less the high degree of hardness, were admitted by the Ancients as half-gems.

Amongst the very complicated minerals (as regards their composition) of this class, *chrysolite* is one of the most simple. This term is applied chiefly to large yellowish green crystals of the substance; to the darker green varieties the name *peridot* is given; while, under the name of *olivine*, the substance is found disseminated throughout many rock masses, especially the basalts (as those of Fingal's Cave, Giant's Causeway, &c.), and also in meteorites. In meteorites from the desert of Atacama, crystals of chrysolite are found. The average chemical composition of this and other minerals of the same class is given in the following table:—

	Si.	Al.	Fe.	Mg.	Ca.	Na.	K.	
FELSPAR (Adularia) ..	65.69	17.97	—	—	1.34	1.01	13.99	Mn
Ditto (Amazon stone) ..	65.32	17.89	0.30	0.09	0.10	2.81	13.05	0.19
			Fe.					
CHRYSOLITE ..	40.12	0.14	15.32	44.34	—	Cr	—	0.29
GARNET (Bohemian) ..	42.08	20.00	1.51	10.20	1.99	3.01	—	0.32
						Beryllia.		
BERYL (Ural) ..	67.00	16.50	1.00	—	0.50	14.50	—	—
Emerald (Muzo) ..	68.50	15.75	1.00	Fl	0.25	12.50	0.50	—
TOPAZ (Brazil) ..	34.24	57.45	—	15.06	{ Zirconia. }	—	—	—
ZIRCON ..	32.00	—	2.00	—	64.5	—	—	—

Felspar is now employed as a family name for a series of minerals. *Orthoclase* is one of these, which, as the name implies, cleaves with right angles. *Adularia* is another variety, named from Aduli, a mountain in Switzerland; its formula is—

One variety of adularia, from its peculiar luminosity, is known as *moon-stone*; and a green variety, from Siberia, as *Amazon-stone*. The porphyries are a peculiar class of rocks containing more or less distinct crystals of various substances in the different varieties; in some districts they are worked as building-stones. A schorlaceous variety, met with only in one district in Cornwall, was employed as the material for the sarcophagus of the Duke of Wellington. Under certain circumstances, felspathic rocks are decomposed, and form the substance known as "kaolin," or "China clay," so largely used by the Chinese for making the finer kinds of porcelain, and, since its discovery in Cornwall and Devon in the last century, applied to the same purpose in this country.

One of the most common of the silicate gems is the *garnet*, which occurs in crystals of large size in many countries. It crystallises as a rhombic dodecahedron, icositetrahedron, and other allied forms, and its formula, in the variety known as *grossularia*, is—

The term garnet is, by jewellers, confined to those stones cut into facets; other specimens of the same mineral, of a deep red colour, when cut *en cabochon* (a jeweller's term to denote a form with rounded faces, or concavo-convex), are known as *carbuncles*. Crystals of it are found in Scotland, but it occurs most abundantly in Hungary, where it is found (especially after floods) in the gravel of rivers. As an example of its abundance there, the lecturer stated that he had bought garnets by the pint from persons in the streets, and that the people there use the small garnets, in the same way as sand is used in some countries, to dry their writing instead of blotting-paper. The *topaz* is another gem of this series, having a crystal-line form, in many cases of a four-sided prism terminated

by a rhomb, and with the property of cleavage well developed in directions parallel to the two ends of the crystal. The cleavage-planes are the smoothest and most brilliant faces of the crystal in its natural state, the sides of the prism being minutely striated, and by these simple properties this gem may be distinguished from several other substances which in some respects closely resemble it. It is found in Siberia, in Brazil, and on a small scale in our own islands at St. Michael's Mount, in Cornwall, and in the Mourne Mountains, in Ireland. A very fine collection of specimens from Siberia is now in the British Museum, having been purchased from a Russian officer, Colonel de Kokscharow; they have, however, to be covered with close-fitting caps, to exclude the light, which would prove injurious to their colour. It has generally a yellowish tint, but is sometimes colourless; the pink varieties are artificially produced by exposure to heat. Its chemical formula is given as—

The gem known to the Ancients under this name appears not to have been the same as that to which we give the name "topaz," but perhaps the crysolite.

The mineral called *beryl*, which includes amongst its varieties the emerald and the aquamarine, crystallises principally in a six-sided prism with flat terminations, but often these terminal planes are replaced by other forms. Its formula is—

and the percentage composition of two varieties is given in the table above. *Beryl* occurs as a greenish, bluish, or greyish mineral, either opaque or translucent; its finest green varieties are known to us as "emerald," while a paler species is termed "aquamarine," as bearing a fancied resemblance in colour to sea-water. As *emerald*, it is very highly valued, and the Ancients were very high in their praises of it; though there is very much difficulty in ascertaining the exact locality whence they obtained it, there is reason to believe that some specimens were from a district in Upper Egypt. Their strange traditions about its being jealously guarded by griffins are capable of a probable rational explanation. They also probably confounded, in many instances, a very different mineral, known as "copper emerald" (having a similar appearance), with the genuine stone; and, indeed, the inferior mineral is now sometimes mistaken and offered for sale as real emerald. The finest emeralds of the present day are brought from Muzo, a district in New Granada, where it is found imbedded in a black limestone. A very fine cylindrical specimen of this gem is set in the tiara of the Popes.

NOTICES OF BOOKS.

A Practical Treatise on Pure Fertilisers, and the Chemical Conversion of Rock Guanos, Marlstones, Coprolites, and the Crude Phosphates of Lime and Alumina generally, into Various Valuable Products. By CAMPBELL MORFIT, M.D., F.C.S. London: Trübner and Co.

THE need of a thoroughly practical work on the manufacture of chemical manures has long been felt. We are happy to find that the deficiency has been supplied by Mr. Campbell Morfit, a chemist who has for years directed his attention to this important subject. It is interesting to find that the author pronounces the sewage of towns to be the true manure, and regards "superphosphate" and similar preparations as mere temporary substitutes, to be laid aside as soon as the great sewage question is thoroughly solved. This solution, we are happy to find, he seeks not in "irrigation," but in "precipitation."

Mr. Morfit points out clearly the defects attending the ordinary system of rendering phosphatic minerals soluble. Commercial "superphosphate," he shows, contains more

or less of the raw material in an unconverted state, along with a variable amount of free acid. Its greatest possible proportion of soluble phosphate is 32 per cent, whilst in ill-made and adulterated samples this constituent may fall as low as 10 or 15 per cent. The phenomenon known as "going back," so unpleasant both to producers and consumers, he ascribes to the presence of unconverted material. "It is the undecomposed portion of triphosphate of lime," he observes, "which exists almost invariably in the ordinary commercial superphosphates, that causes the biphosphate portion to 'go back,' according to trade language, or become directly insoluble in water."

In place of these superphosphates the author recommends "precipitated phosphate," "Columbian phosphate," diphosphate, chlorophosphate, and sulphited phosphate. The processes for preparing these fertilisers, as directed by Way, Deligny, Gerland, and the author himself, are clearly described, with the addition of diagrams of the machinery and plant required, drawn to scale. For Gerland's "sulphited phosphate" he claims a very high rank as a disinfectant and deodoriser, and points out the ease with which it can be manufactured in regions where acids are not procurable. In its production he tells us—"Sulphuretted ores may be substituted for sulphur; and this means of concentrating them, by roasting, for more economical transportation to distant markets or smelting-works, opens a way for the profitable production of the sulphite of tri-phosphate of lime in those remote places where crude phosphate material abounds, and sulphuric acid is to be obtained only at a cost which is too great for its employment in the usual processes of manufacturing fertilisers."

It must, however, be admitted that to introduce these "pure fertilisers" into the market will be a work of time and of difficulty. One reason why so many low-class manures are made and sold is the outcry for cheapness. Double the strength of your product, and you will not always find it practicable to obtain double the price.

The author furnishes a list of normal fertilisers adapted for different crops, which may, we think, be advantageously studied alike by manure manufacturers and farmers.

In his valuable sections on the analysis of manures and phosphatic minerals, Mr. Morfit makes a remark which cannot be too widely circulated:—"The phosphoric acid is thus shown in its individual combinations, and not totalised as tri-phosphate of lime, according to the mercenary style of 'commercial' chemistry."

Without declaring ourselves satisfied with every view advanced in these pages—especially as regards the cost of producing manures—we can conscientiously recommend the work to the careful study of all our readers who are interested in the application of chemistry to the oldest and most important of the arts.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, December 9, 1872.

In addition to papers relating to mathematico-physical and natural history sciences, this number contains the following original papers and memoirs relating to chemistry:—

Observations on some Groups of Isomeric Substances Derived from the Fermentation Alcohols.—I. Pierre and E. Puchot.—This exhaustive essay, elucidated by a large number of

boiling-point, 265° to 270° . Butyl-dioxysulpho-carbonate—

Semi-sulphuretted butyl-urethan—
 $\text{C}_4\text{H}_9\text{O} \cdots \text{CS}.$

Semi-sulphuretted phenyl-butyl-urethan—
 $\text{NH}_2 \cdots \text{CS}.$
 $\text{C}_6\text{H}_5\text{O} \cdots \text{CS}.$
 $\text{N} \left\{ \begin{array}{l} \text{C}_4\text{H}_9 \\ \text{C}_6\text{H}_5 \end{array} \right\} \cdots \text{CS}.$

The mode of preparation of these substances is minutely described.

Contribution to our Knowledge on Butyl-Sulphydrate.—E. Mylius.—While the author's researches confirm those of Humann (*Ann. Chem. Pharm.*, vol. xcv., p. 256) on the action of nitric acid upon isobutyl-mercaptan, the main product of the action of nitric acid at 130° sp. gr. upon the mercaptan just mentioned is the formation of isobutyl-sulpho acid—

the salts of this acid are very soluble in water. The silver salt—

is a crystalline body; the barium salt—
 $(\text{C}_4\text{H}_9\text{SO}_2)_2$

is very soluble and crystalline; the lead-salt cannot be obtained in pure state, since basic salts are formed of an indefinite composition.

Action of Phosphorus upon Alkaline Metallic Solutions.—A. Oppenheim.—Reserved for full translation.

Polytechnisches Journal von Dr. E. M. Dingler, first number for November, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Researches on the Gold Assay as Practised at Mint-Works.—Dr. H. Rösler.—This essay, elucidated by several tables exhibiting the results of experiments, treats at length on the ordinary gold assay (by the dry way). The general result of the author's researches is that, *ceteris paribus*, gold of lower purity (more alloyed), which has to be treated with much lead, will yield on cupellation a worse result than a purer alloy when treated precisely in the same way; and further, that when, by the fine-gold test (*feingold probe*), the loss of gold is compensated for by the quantity of silver retained, the loss of gold, when more base alloys are assayed, exceeds the quantity of silver retained—in other words, that the results of cupellation in the latter case always indicate too low a quantity of gold.

The Future of the Gold-Plating Industry.—Dr. C. Winkler.—This essay treats on the present state of this industry in Germany, and on the improvements still to be made in the manufacture of imitation jewellery.

Industrial Method of Withdrawing the Fuel Oil from Crude Spirits by means of Charcoal.—Dr. W. Schultze.—This lengthy paper enters into minute details on the following matters:—Preparation of the charcoal; the size of the lumps of the charcoal and the process of operating; on the influence of the air in the pores of the charcoal; the influence of the porosity of the coal; defusellation and the degree of dilution of the spirit; defusellation and the duration of contact between charcoal and spirits.

The Methods of Petroleum Collection (viz., from the Soil by Borings, &c.) in Use in America and Galicia.—A. Fauck.

Filters Made from Spun and Felted Glass.—P. Weiskopf.—At the request of the Austro-Hungarian government, the author has made a series of experiments to ascertain whether finely-spun glass-thread can be felted and made into a suitable shape for the purpose of filtering. The author has used pure hard Bohemian glass for this purpose, and finds it to answer exceedingly well and to filter rapidly, as well as yielding a perfectly clear filtrate. The author will send glass wool, as he terms it, from his residence at Morchenstern, in Bohemia, to those who feel interested in this matter.

Second number for November, 1872.

This number contains the following original matter relating to chemistry and collateral subjects:—

Calcining Furnaces Invented by Hasenclever and Helbig for the Purpose of Desulphurising Ores so that the Sulphur may be used for Sulphuric Acid Preparation.—R. Hasenclever.—This memoir, illustrated by engravings, contains the detailed description of a furnace so constructed that the metallic ores which contain little or less sulphur can be so calcined that the sulphur may be readily utilised for the preparation of sulphuric acid.

Theory of the Nucleus Formation (Kernbildung) during the Roasting of Cupreous Pyrites.—A. Schertel.

Essay Containing an Enumeration of the German and Best Known Foreign Clays (for Ceramic Purposes) According to their Geological Occurrence in the Tertiary and Older Formations.—Dr. C. Bischof.—This essay contains a review of the various and best known clays used for ceramic purposes.

Softening of Water by the Aid of Lime-water.—J. Stingl.—This monograph, elucidated by a series of results of analyses of water, treats on the precipitation of a large proportion of the dissolved

earthy matters contained in natural waters by the aid of lime-water, which has, however, to be used only in comparatively small quantity, to be regulated by the composition of the solid matter dissolved in the water.

Preparation of Fuchsin without Arsenic Acid.—Dr. Dingler.—It appears that at the extensive aniline pigment factory of Messrs. Meister, Lucius, and Brünig at Höchst-on-the-Main, the aniline oil is converted into rosaniline by the aid of nitro-benzol. This process, which yields excellent results, may be elucidated by the following formulæ:—

Analysis of Raw Sugar, and on the Means by which more Concordant Results may be Obtained by Different Analysts.—Dr. C. Kohlrausch.—Illustrated with woodcuts.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, October, 1872.

In addition to several papers strictly relating to pharmaceutical science, this number contains the following papers and memoirs bearing upon chemistry:—

Chemical Investigation of the Fruit of the Barberry (*Berberis Vulgaris*).—Dr. Graeger.—Leaving the stalks, the berries consist, in 100 parts, of—Husks and seeds, 15.58; soluble matter, 17.20; water, 67.22. Chemical composition of the fruit, in 100 parts:—Husks and seed, 15.58; free malic acid, 5.92; grape sugar, 4.67; gum, 6.61; ash of juice, 0.06; water, 67.16; total, 100. Ash of the husks and seeds, 2.20 per cent.

On Hyoscyamine.—Dr. G. Merck.—After observing that this alkaloid is mostly described as a crystalline solid, the author states that more recent research has proved the hyoscyamine only to be obtainable as an amorphous mass, but he adds that if this is gently submitted to distillation with hot water, there is obtained a colourless oily fluid, similar to coniine. This modification of hyoscyamine is readily soluble in alcohol, ether, and water, but only partly soluble in benzol and chloroform. By exposure to air, the fluid hyoscyamine (which exhibits a strong alkaline reaction and neutralises acids completely) becomes dark coloured, thickish, and emits an unpleasant smell. In that condition the hyoscyamine is not more soluble in ether. The oxalate of this base was obtained in crystalline form.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents, 54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

3272. J. R. Williams, Manchester, "Improvements in cements."—Petition recorded November 4, 1872.

3278. W. Glazier, Rochdale, Lancashire, "Improvements in treating and utilising certain refuse animal and vegetable substances, and the application of the resulting substances or matters to various manufactures."—Petition recorded November 5, 1872.

3288. H. Harrison, Killalea, Tipperary, Ireland, "Improvements in the manufacture of artificial or prepared fuel from anthracite dust or 'culm,' or from other coal dust, and in apparatus employed in such manufacture."—Petition recorded November 6, 1872.

3330. A. C. Pelly, Finch Lane, London, "Improvements in the manufacture of peat fuel, and in the machinery and apparatus therefor."—A communication from L. Von Horn, Stockholm.—Petition recorded November 9, 1872.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.
Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The LABORATORY will be open at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1869, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ship's Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian and other Governments.

Methylated Spirits.—David Smith Kidd, Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Royal Polytechnic.—Great Programme for Christmas.—1. The History of a PLUM PUDDING, with striking experiments by Professor Gardner. 2. A Christmas Tale: or, HOW JANE CONQUEST RANG THE BELL; an Illustrated Poem, with remarkable effects. 3. The "ZOO" at the "POLY," an anecdotal discourse about the Zoological Gardens, by Mr. J. L. King, with Photographs by Mr. York. 4. The THREE ROSES; or the Invisible Prince in a new light: a fairy tale, musically narrated by Mr. George Buckland, assisted by Miss Alice Barth, Miss Pulham and Miss Lillie Bartlett. 5. The WHITE LADY of AVENEL the new and beautiful Ghost Illusion. 6. New CHARACTER ENTERTAINMENT, by Mr. Percy Vere. 7. The wonderful SWIMMING FEATS of Marquis Bibbero in the Great Tank. 8. The MAGIC TUB, full of Toys, to be distributed, on specific occasions, to good children. Many other Entertainments. Open daily, at 12 and 7. Admission, 2s.

boiling-point, 265° to 270° . Butyl-dioxysulpho-carbonate—

Semi-sulphuretted butyl-urethan—

Semi-sulphuretted phenyl-butyl-urethan—

The mode of preparation of these substances is minutely described.

Contribution to our Knowledge on Butyl-Sulphydrate.—E. Mylius.—While the author's researches confirm those of Humann (*Ann. Chem. Pharm.*, vol. xcv., p. 256) on the action of nitric acid upon isobutyl-mercaptan, the main product of the action of nitric acid at 130° sp. gr. upon the mercaptan just mentioned is the formation of isobutyl-sulpho acid—

the salts of this acid are very soluble in water. The silver salt—

is a crystalline body; the barium salt—
 $(\text{C}_4\text{H}_9\text{O})_2\text{SO}_3\text{Ba}$
is very soluble and crystalline; the lead-salt cannot be obtained in pure state, since basic salts are formed of an indefinite composition.

Action of Phosphorus upon Alkaline Metallic Solutions.—A. Oppenheim.—Reserved for full translation.

Polytechnisches Journal von Dr. E. M. Dingler, first number for November, 1872.

This number contains the following original papers and memoirs relating to chemistry and collateral subjects:—

Researches on the Gold Assay as Practised at Mint-Works.—Dr. H. Rösler.—This essay, elucidated by several tables exhibiting the results of experiments, treats at length on the ordinary gold assay (by the dry way). The general result of the author's researches is that, *ceteris paribus*, gold of lower purity (more alloyed), which has to be treated with much lead, will yield on cupellation a worse result than a purer alloy when treated precisely in the same way; and further, that when, by the fine-gold test (*Feingold probe*), the loss of gold is compensated for by the quantity of silver retained, the loss of silver retained—in other words, that the results of cupellation in the latter case always indicate too low a quantity of gold.

The Future of the Gold-Plating Industry.—Dr. C. Winkler.—This essay treats on the present state of this industry in Germany, and on the improvements still to be made in the manufacture of imitation jewellery.

Industrial Method of Withdrawing the Fusel Oil from Cruc Spirits by means of Charcoal.—Dr. W. Schultze.—This lengthy paper enters into minute details on the following matters:—Preparation of the charcoal; the size of the lumps of the charcoal and the process of operating; on the influence of the air in the pores of the charcoal; the influence of the porosity of the coal; defuselisation as the degree of dilution of the spirit; defuselisation and the duration of contact between charcoal and spirits.

The Methods of Petroleum Collection (viz., from the Soil to Salt Borings, &c.) in Use in America and Galicia.—A. Fauck.

Filters Made from Spun and Felted Glass.—P. Weiskopf.—At the request of the Austro-Hungarian government, the author has made a series of experiments to ascertain whether finely-spun glass thread can be felted and made into a suitable shape for the purpose of filtering. The author has used pure hard Bohemian glass for this purpose, and finds it to answer exceedingly well and to filter rapidly as well as yielding a perfectly clear filtrate. The author will send glass wool, as he terms it, from his residence at Morchenstern, in Bohemia, to those who feel interested in this matter.

Second number for November, 1872.

This number contains the following original matter relating to chemistry and collateral subjects:—

Calcining Furnaces Invented by Hasenclever and Helbig for the Purpose of Desulphurising Ores so that the Sulphur may be used for Sulphuric Acid Preparation.—R. Hasenclever.—This memoir, illustrated by engravings, contains the detailed description of a furnace so constructed that the metallic ores which contain more or less sulphur can be so calcined that the sulphur may be readily utilised for the preparation of sulphuric acid.

Theory of the Nucleus Formation (Kernbildung) during the Roasting of Cupreous Pyrites.—A. Schertel.

Essay Containing an Enumeration of the German and Best Known Foreign Clays (for Ceramic Purposes) According to their Geological Occurrence in the Tertiary and Older Formations.—Dr. C. Bischof.—This essay contains a review of the various and best known clays used for ceramic purposes.

Softening of Water by the Aid of Lime-water.—J. Stingl.—This monograph, elucidated by a series of results of analyses of water, treats on the precipitation of a large proportion of the dissolved

earthy matters contained in natural waters by the aid of lime-water, which has, however, to be used only in comparatively small quantity, to be regulated by the composition of the solid matter dissolved in the water.

Preparation of Fuchsin without Arsenic Acid.—Dr. Dingler.—It appears that at the extensive aniline pigment factory of Messrs. Meister, Lucius, and Brünig at Höchst-on-the-Main, the aniline oil is converted into rosaniline by the aid of nitro-benzol. This process, which yields excellent results, may be elucidated by the following formula:—

Analysis of Raw Sugar, and on the Means by which more Concordant Results may be Obtained by Different Analysts.—C. R. Kohlrusch.—Illustrated with woodcuts.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, October, 1872.

In addition to several papers strictly relating to pharmaceutical science, this number contains the following papers and memoirs bearing upon chemistry:—

Chemical Investigation of the Fruit of the Barberry (*Berberis Vulgaris*).—Dr. Graeger.—Leaving the stalks, the berries consist, in 100 parts, of—Husks and seeds, 15.58; soluble matter, 17.20; water, 67.22. Chemical composition of the fruit, in 100 parts:—Husks and seed, 15.58; free malic acid, 5.92; grape sugar, 4.67; gum, 6.61; ash of juice, 0.06; water, 67.16; total, 100. Ash of the husks and seeds, 2.20 per cent.

On Hyoscyamine.—Dr. G. Merck.—After observing that this alkaloid is mostly described as a crystalline solid, the author states that more recent research has proved the hyoscyamine only to be obtainable as an amorphous mass, but he adds that if this is gently submitted to distillation with hot water, there is obtained a colourless oily fluid, similar to conine. This modification of hyoscyamine is readily soluble in alcohol, ether, and water, but only partly soluble in benzol and chloroform. By exposure to air, the fluid hyoscyamine (which exhibits a strong alkaline reaction) gradually and completely becomes $2(\text{C}_{22}\text{H}_{26}\text{N}_4\text{HCl})\text{PtCl}_4$.

Free Base.—In order to prepare some other salts of safranin it was necessary to obtain the free base. When we first commenced the study of this new compound, remembering the properties of the tinctorial ammonias in general, we endeavoured to precipitate the base from the chlorhydrate by alkalis. Ammonia, however, is without any action whatever over salts of safranin; and only in the most concentrated solutions does soda produce a precipitate, which immediately re-dissolves on addition of water. This precipitate is obviously nothing but chlorhydrate rendered insoluble by the sodium chloride formed, or by the concentrated soda solution. Free safranin being soluble in water, there remained no other process for liberating the base than treatment of the chlorhydrate with silver oxide. On evaporating the deep yellow-red coloured liquid obtained in this way a deposit of red-brown crystals is formed on cooling, which while moist scarcely differ from those of the chlorhydrate, but when dried at 100° , assume a greenish metallic lustre. Free safranin easily dissolves in water and alcohol, but is insoluble in ether. Addition of chlorhydric acid to the aqueous solution at once reproduces the crystalline chlorhydrate. We have not been fortunate enough to obtain free safranin in a state

in which it can be obtained.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.R.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

BERNERS COLLEGE of CHEMISTRY.—

EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.R.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.

Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.

Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The LABORATORY will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fees to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

the GRAND DIPLOMA of HONOUR, being the First Prize, and superior to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar, sold by all Italian Warehousemen, Grocers, Chemists, and Shipstore Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT MEAT COMPANY (LIMITED), 43, MARK LANE, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be very superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian and other Governments.

Methylated Spirits.—David Smith Kidd,

Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda

and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Royal Polytechnic.—Great Programme for

Christmas.—1. The History of a PLUM PUDDING, with striking experiments by Professor Gardner. 2. A Christmas Tale: or, HOW JANE CONQUEST RANG THE BELL; an Illustrated Poem, with remarkable effects. 3. The "ZOO" at the "POLY," an anecdotal discourse about the Zoological Gardens by Mr. J. L. King, with Photographs by Mr. York. 4. The THREE ROSES; or, the Invisible Prince in a new light: a fairy tale, musically narrated by Mr. George Buckland, assisted by Miss Alice Barth, Miss Pulham, and Miss Lillie Bartlett. 5. The WHITE LADY OF AVENUE, the new and beautiful Ghost Illusion. 6. New CHARACTER ENTERTAINMENT, by Mr. Percy Vere. 7. The wonderful SWIMMING FEATS of Marquis Bibbero in the Great Tank. 8. The MAGIC TUB, full of Toys, to be distributed, on specified occasions, to good children. Many other Entertainments. Open daily, at 12 and 7. Admission, 1s.

THE CHEMICAL NEWS.

VOL. XXVI. No. 683.

COLOURING-MATTERS DERIVED FROM AROMATIC AZODIAMINES.*

By A. W. HOFMANN, Ph.D., F.R.S., and A. GEYGER, Ph.D.

II. SAFRANINE.

WHILST we were engaged with the study of the blue colouring-matters produced by the action of aromatic monamines on azodiphenyldiamine, our attention became directed to a beautiful red tar-pigment, which has been known for some time by the commercial name of safranine, being extensively used as a substitute for safflower in dyeing silk and cotton. Safranine has not as yet been minutely examined; but, as far as can be judged from the scanty information we possess regarding its production, it is scarcely doubtful that this important dye must be looked upon as being the derivative of an azodiamine. The analyses of safranine thus promised to throw considerable light upon the nature of the compounds under examination.

The starting-point of our studies was the dye such as it occurs in commerce. The greater portion of it was supplied to us by Messrs. Tillmanns, in Cryfeld. Another specimen was received from Dr. T. Wolf, and for a third we are indebted to our friend M. Charles Girard, in Paris. Both the first-mentioned specimens were assigned to us as produced on the large scale; the last was prepared by M. Girard himself.

Safranine occurs in commerce either as a solid body or *en pate*. In the solid state it forms a yellowish-red powder, in which, together with considerable quantities of chalk and common salt, the chlorhydrate of a tinctorial base has been recognised. The pure dye may be easily separated from the crude safranine. It is only necessary to exhaust the commercial product with boiling water; on cooling, the filtrate deposits a slightly crystalline substance, which, after several re-crystallisations from boiling water, leaves no residue on ignition. During these operations, however, the salt undergoes perceptible alteration; with every re-crystallisation it becomes more soluble and less crystalline. These alterations depend upon the separation of chlorhydric acid from the salt. In fact the percentage of chlorine is found to diminish in the product of successive crystallisations; thus the product of the third contained 8.48 per cent, that of the fourth crystallisation only 7.46 per cent. Addition of chlorhydric acid to the mother-liquors at once reproduces a crystalline precipitate. This instability of the chlorhydrate, and in fact, as may even now be stated, of the salts of safranine in general, has very considerably impeded the study of this body, and often materially affected the accuracy of the analytical results. In order to obtain the normal salt, the boiling liquid during the last crystallisation had always to be acidified with chlorhydric acid.

Safranine chlorhydrate separates in fine reddish crystals from the acid solution on cooling; an appreciable quantity of the compound, however, remains in solution. The salt dissolves both in water and alcohol more readily when hot than when cold; it is insoluble in ether, as also in concentrated saline solutions. The alcoholic solution, like the aqueous, is of a deep red-yellow colour; it exhibits a peculiar fluorescence, which in a measure recalls that of Magdala-red. Ether precipitates the salt from the alcoholic solution. Numerous analyses which

we have made of this salt lead to the following two formulæ:—

the theoretical values of which agree almost equally well with the averages of the experimental numbers. We were doubtful at first to which of these two formulæ preference should be given. Indeed the assumption of twenty atoms of carbon in the molecule of safranine had its seductions; however, the values of the second formula agreed perhaps somewhat better with the results of analyses. Indeed we found invariably somewhat less nitrogen than the quantity required by the former formula, whilst it is well known that the volumetric method invariably gives an excess; so that we should have adopted the second formula, even if later experiments on the preparation of safranine had not altogether excluded the former one.

Platinum Salt of Safranine.—The numbers obtained in the analysis of the chlorhydrate are confirmed by the investigation of the platinum salt. This compound is obtained by precipitating a solution of the chlorhydrate by excess of platinum perchloride; dilute hydrochloric acid must be used to wash this precipitate, as pure water appears to decompose it. The platinum salt forms a yellowish-red crystalline powder, nearly insoluble in water, alcohol, and ether.

If the salt suspended in boiling water be treated with sulphhydric acid, sulphide of platinum is slowly formed, whilst unaltered chlorhydrate of safranine remain in solution. The analysis of the salt, dried at 100°, gives numbers corresponding to the formula—

Free Base.—In order to prepare some other salts of safranine it was necessary to obtain the free base. When we first commenced the study of this new compound, remembering the properties of the tinctorial ammonias in general, we endeavoured to precipitate the base from the chlorhydrate by alkalis. Ammonia, however, is without any action whatever over salts of safranine; and only in the most concentrated solutions does soda produce a precipitate, which immediately re-dissolves on addition of water. This precipitate is obviously nothing but chlorhydrate rendered insoluble by the sodium chloride formed, or by the concentrated soda solution. Free safranine being soluble in water, there remained no other process for liberating the base than treatment of the chlorhydrate with silver oxide. On evaporating the deep yellow-red coloured liquid obtained in this way a deposit of red-brown crystals is formed on cooling, which while moist scarcely differ from those of the chlorhydrate, but when dried at 100°, assume a greenish metallic lustre. Free safranine easily dissolves in water and alcohol, but is insoluble in ether. Addition of chlorhydric acid to the aqueous solution at once reproduces the crystalline chlorhydrate. We have not been fortunate enough to obtain free safranine in a state of perfect purity; the solution invariably retains a small quantity of silver chloride, which separates with the crystallising product; it may be recognised by burning the base, when a small incombustible residue is left. If the chlorhydrate be reproduced from the free base, so much silver chloride is mixed with the salt, that the percentage of chlorine, found on analysis, is appreciably raised. An estimation of chlorine in the chlorhydrate thus prepared gave 10.8 per cent, instead of 9.74. Free safranine, however, may be used without difficulty in the preparation of other salts, the nitrate for instance.

Safranine nitrate is easily obtained when an excess of dilute nitric acid is added to a hot aqueous solution of the free base. On cooling the salt crystallises in red-brown needles, which are very insoluble in cold but readily dissolve in boiling water. They are considerably more soluble in alcohol than in water. The nitrate is decidedly less soluble than the chlorhydrate; a solution from which the latter salt has been thrown down by

* A Paper read before the Royal Society.

chlorhydric acid still gives a precipitate with nitric acid. The analysis of the nitrate, dried at 100°, leads to the formula $C_{21}H_{21}N_5O_3 = C_{21}H_{20}N_4 \cdot HNO_3$.

Safranine picrate.—We have finally investigated the picrate. It is obtained by simply adding an aqueous solution of picric acid to the mother-liquors of the chlorhydrate or nitrate, and washing the precipitate thus formed with water. The picrate forms red-brown needles, which are insoluble in water, alcohol, and ether.

The analysis gave results corresponding to those obtained in the investigation of the chlorhydrate of the platinum salt and of the nitrate, and leading to the formula $C_{27}H_{23}N_7O_7 = C_{21}H_{20}N_4 \cdot C_6H_3(NO_2)_3O$. We have no further analytical data to offer at present. A brief notice of several other salts we have prepared may, however, still be appended.

Safranine bromhydrate is deposited on addition of bromhydric acid to a solution of the base, as a crystalline powder, consisting of microscopic needles, which are so insoluble in water that the liquid from which they have been precipitated appears almost colourless. The salt is soluble in boiling water, from which it crystallises on cooling. It is worth mentioning that, on adding bromine water to a solution of the chlorhydrate, a red crystalline precipitate is formed, which is difficultly soluble in cold water, but may re-crystallise from boiling water. In this way needle-shaped crystals are obtained which, when pure, possess a green metallic lustre. They have not yet been analysed.

The **iodhydrate**, as regards preparation and properties, is perfectly similar to the bromhydrate.

The **sulphate of safranine** is a tolerably soluble salt: only in the most concentrated aqueous solution of the base is a precipitate produced on addition of dilute sulphuric acid; the salt dissolves on heating the liquid, and is again deposited on cooling in the form of fine needles.

The **oxalate** behaves very similarly, but is a little less soluble than the sulphate; with acetic acid the base gives no precipitate; by spontaneous evaporation the acetate separates in rather indistinct crystals.

All the salts of safranine exhibited very characteristic reaction; on adding chlorhydric acid to the solution of the salt, the red-brown colour of the liquid changes to a beautiful violet, which, on addition of more acid, becomes a deep blue, then a dark green, and finally bright green; if the acid liquid be slowly diluted with water, these changes of colour may be observed in inverse order.

It need scarcely be mentioned that in the course of this investigation our attention has been repeatedly directed towards the preparation of safranine; it may, however, at once be stated that our experiments on this subject have yielded but scanty results. As yet but little is known regarding the preparation of safranine on a large scale. According to a brief notice published by Mené*, safranine is obtained by treating aniline successively with nitrous and arsenic acids; this process very closely agrees with the method by which M. Girard, as he informs us, has prepared the specimen transmitted to us. We have, moreover, to thank M. Girard for pointing out that aniline of a very high boiling-point is especially adapted to the preparation of safranine.

After some practice we have been able, by working according to these indications, to obtain safranine with all the properties of the commercial product. The yield, however, was always very small, an exceedingly large quantity of little attractive by-products being invariably formed. Somewhat more satisfactory results were obtained when chromic instead of arsenic acid was used as oxidising agent. Our experiments, though unsuccessful as regards the discovery of a good method for preparing safranine, they nevertheless appear to supply some welcome indications as to the real source of the colouring-matter. Neither from pure aniline nor from solid toluidine have we been able to obtain safranine by

the above-mentioned process; nor did a mixture of pure aniline on the solid toluidine yield a better result. We have, however, invariably obtained safranine when liquid toluidine, boiling at 198°, was used for the experiment. This colouring-matter thus appears to become a pure derivative of toluidine, and the formula $C_{21}H_{20}N_4$, to which analyses had led, is corroborated, as far, at all events, as the number of carbon atoms in the molecule of safranine are concerned, in a most satisfactory manner by the formation of this body. In this formation, as in that of rosaniline and of the allied tinctorial ammonias, 3 mols. of monamine associate to a complex molecule, 3 atoms of hydrogen in which are displaced by one of nitrogen, and 4 atoms of hydrogen being, moreover, removed by oxidation.

A glance at the safranine formula with its four nitrogen atoms recalls the composition which Mr. Perkin ascribes to mauveine.

The idea suggests itself that mauveine might be phenyl-safranine, $C_{27}H_{24}N_4 = C_{21}H_{19}(C_6H_5)N_4$. In fact safranine salts yield a violet colouring-matter when boiled for some time with aniline; again, safranine and mauveine exhibit nearly the same changes of colour under the influence of concentrated acids. Further, from a short notice published some years ago by Mr. Perkin,* safranine appears to be a by-product in the preparation of mauveine.

Relations such as suggested by the above formulæ must, however, be received with great caution. The violet colouring-matter derived from safranine has, by phenylation, not as yet been further characterised. No great stress can be laid on the similar colour reactions, with acids, exhibited by both bases; since the methylate rosaniline, on treatment with acids, also becomes first blue and then green. Moreover, it is doubtful whether the base obtained by Mr. Perkin as a secondary product in the manufacture of mauveine really is the same safranine which we have investigated, inasmuch as some preliminary analyses have led him to a very different composition, which appears to be expressed by the formula $C_{18}H_{18}N_4$. Finally, the composition of mauveine itself cannot be looked upon as established above all question; at least Mr. Perkin† seems still to hesitate between the formula $C_{26}H_{24}N_4$, which appears to result from more recent experiments, and the formula $C_{27}H_{24}N_4$, previously announced by him.

The relations here pointed out are, however, well worthy of a thorough experimental investigation. As we intend to continue this inquiry, an opportunity may present itself for their further elucidation.

INDUSTRIAL MANUFACTURE OF CHLORINE.

By F. de LALANDE and M. PRUD'HOMME.

THE reaction of anhydrous sulphuric acid mixed with air or oxygen upon heated alkaline chlorides, which has given rise to Deacon's patent for the preparation of chlorine and of sulphate of soda, has led us to generalise this process. We have chiefly experimented with silicic, boric, stannic, and phosphoric acids, and also with alumina. When any of these bodies, silica, for instance, is mixed with an alkaline chloride, or with an alkaline-earthly or earthy chloride, and over this mixture, while being heated to red heat, a current of dry oxygen or air is passed, chlorine is evolved, and a silicate formed of the base of the chloride

* Mené, from the *Revue Hebdomadaire de Chim. Scient. Indust.*, Feb. 29, 1872, in *CHEMICAL NEWS*, vol. XXV., p. 215.

* Perkin, *Proc. R. Inst. of Great Britain*, vol. V., p. 572.

† Perkin, *loc. cit.*

employed, $\text{SiO}_2 + \text{ClNa} + \text{O} = \text{SiO}_2\text{NaO} + \text{Cl}$. At red heat, therefore, oxygen expels chlorine, when there is simultaneously present an acid capable of uniting with the base which is formed. Chlorides heated by themselves in a current of oxygen (chloride of calcium, for instance) do not give off chlorine. When a current of *hydrochloric acid* gas is passed along with oxygen over the mixture of silica and chloride the acid regenerates the chloride and decomposes the silicate—

In this way a *continuous* evolution of chlorine is obtained. Instead of taking the mixture of chlorine and silica, the silicate of the metal in which the chloride is contained, or a mixture of silica and the oxide of that metal is taken. Since analogous reactions occur with the acids above mentioned, we may state that it is general. The steam formed during the phase of reaction—

gives rise to two secondary actions:—

(1). The chlorine decomposes the water at red heat:—

(2). The steam decomposes the chlorides at red heat:—

It is probable that under these conditions an equilibrium exists between the quantities of chlorine, aqueous vapour, and hydrochloric acid issuing from the apparatus, or a limit of maximum between the quantity of chlorine produced and the hydrochloric acid evolved and issuing from the apparatus. This limit of maximum will be the greater according as the temperature required for the reaction be less high. Some of our experiments having been made by causing the substances operated with to be imbibed by pumice-stone, we have been induced to try whether pumice-stone alone would yield any result, that material being a complex silicate and a substance belonging to the category of those indicated by us. We have found that with pumice-stone an evolution of chlorine is obtained comparable to that obtained from the other substances, more particularly silica and lime, boric acid and lime, stannic acid and lime, alumina and chloride of sodium; since the same result is obtained with lumps of brick, it might be ascribed to the porosity of these substances; but this opinion is gainsayed by the fact that under the same conditions pipe-clay, a silicate of alumina and a very porous body, does not give rise to any appreciable reaction; it therefore appears possible that hydrochloric acid converts the surface of pumice-stone into a mixture of silica and chlorides. We have compared the production of chlorine in our experiments with that obtained by using bricks impregnated with sulphate of copper (Deacon's patent); the quantity of chlorine obtained in both cases is the same; but with bricks impregnated with sulphate of copper the reaction takes place at a lower temperature. The imperfection of our apparatus has hitherto prevented us from estimating the respective quantities of chlorine, hydrochloric acid, aqueous vapour, contained in the gases issuing from the apparatus; neither have we been able to estimate exactly the degree of temperature at which the reactions take place.

MINERALOGY.

MR. W. W. SMYTH, F.R.S., took for the subject of his fifth lecture of the course to working men, delivered on Monday, December 9th, "Carbon and Coals."

The substances of which he proposed to speak were all characterised by consisting wholly or principally of carbon, although differing very much in their outward forms. The diamond is a crystallised form of pure carbon, remarkable from the earliest times for its great brilliancy and extraordinary hardness. Its hardness is so great as to render

it capable of cutting or scratching all other substances; and this character has lately been taken advantage of in a very ingenious application of the diamond to boring or drilling holes through hard rock masses. For this purpose a number of pieces of diamond—of course of the inferior qualities—are set in a ring round the end of a tube, and it is found that by this means very rapid progress can be made, compared with that accomplished by the use of steel tools alone. The simplest crystalline form assumed by the diamond is that of octahedron, very frequently with the edges a little worn and rounded; and the more complicated crystals are all capable of being split parallel to the faces of the octahedron. This property of splitting is taken advantage of to obtain fragments with sharp edges for cutting purposes. The great brilliancy of the diamond is due entirely to the very great refractive power; on account of which, many of the rays of light falling upon a piece of diamond are so much refracted as to be reflected from the interior, and when the diamond is cut into suitable facets, the brilliancy is so great as to have obtained for the form the name of "brilliant." The origin of the diamond is not yet cleared up. It is found in the detrital matter brought down by streams in parts of Brazil, India, and the Cape of Good Hope.

Graphite (from *grapho* to write) is a substance exactly like diamond in its chemical composition, but very different in outward appearance and its crystalline form. The latter is very distinct, being chiefly that of minute hexagonal scales, the minuteness and incoherence of which render it usually so soft, and also enable it to be employed as an anti-frictional material. Thus we have two substances formed of the same material carbon, but at opposite extremities of the scale of hardness. Varieties of it are found containing from 90 to 95 per cent of carbon; the remainder is impurity in the shape of iron oxide, &c. It is now, especially in some parts of Central Europe, in great request for the manufacture of crucibles, in consequence of its great degree of infusibility. The purest kinds of it are not, as people used to believe, confined to Borrowdale in Cumberland; enormous quantities are now raised and imported from Ceylon, Canada, Bavaria, Bohemia, &c.

In coals,—which taken on the large scale are far more important to us than the diamond—the carbon loses its distinct crystalline state, and is mixed more or less with other materials. The lecturer then briefly explained the manner in which the coal occurs, viz., in bands or layers, technically known as "coal-seams" of various thicknesses, alternating with other strata of indurated clay, known as shale, and of grey sand-stone, called grit. At the base of each bed of coal is found a bed of clay, which contains the fossil roots of the plants from which the coal has been formed. The beds are not in all cases horizontal, though originally deposited so, but have been tilted up into various positions. They vary, too, a great deal in thickness, being in some cases too thin to be profitably worked, i.e., under present conditions. The following list gives the number of workable seams, and the average total thickness of them in several localities for purposes of comparison. South Wales, 57 seams, 179 feet thick: North Staffordshire, 62 seams, 165 feet; Derbyshire, 40 seams, 86 feet; Newcastle, 16 seams, 50 feet; Westphalia, 83 seams, 173 feet; Saarbruck, 164 seams, 338 feet. It will be seen that the supply to the Newcastle field is strictly limited; the adjoining Durham coal-field has lately been proved beneath the sea.

On examining a lump of coal, it may be frequently be observed to be made up of a series of parallel laminæ, sometimes as many as 20 to an inch. Sometimes these layers are alternately bright and dull, and are really two distinct varieties of coal, one burning with far more flame and smoke than the other. These laminæ are, or have been, more or less horizontal, but in some districts there is also a set of parallel divisional planes running in a direction at right angles to the first set of laminæ. These are of great value and importance to the miner in getting the coal, for

by taking advantage of these planes he can obtain a larger proportion of large coal than if he has to break down irregular lumps with his pick. Occasionally, a third set of parallel lines occurs at right angles to the last set, and then the coal breaks into more or less cuboidal or rhomboidal blocks with smooth faces.

If we classify coals according to their proportions of carbon, which is the heat-giving element, and therefore the measure of their quality as fuel, we have first anthracite or stone coal, with 90 to 98 per cent of carbon, worked amongst other places in the west part of the South Wales coal field. It is rather difficult to light, but makes extremely hot fires when fairly set going. Next come the steam, smokeless, or free burning coals, worked round Merthyr-Tydvil and Aberdare, which are highly valued for steamers, and especially for men-of-war. Then comes a great series of coals such as are found in the Midland Counties, and supplied to most parts for household purposes. These are more or less bituminous, burning with a greater quantity of flame and smoke than either of the two preceding varieties. Cannel coal does not soil the fingers, and is capable of taking a fair polish. It is worked in large quantities about Wigan in Lancashire. Lignite, or brown coal, is an intermediate state between true wood and true coal, having frequently a texture and appearance much like wood. It contains less carbon and more gaseous matters than true coal, and gives off a great deal of smoke. It occurs in Saxony, and Bohemia, &c., on the Continent; and on a small scale in England, at Bovey Tracey.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 19th, 1872.

Prof. WILLIAMSON, F.R.S., Vice-President, in the Chair.

AFTER the minutes of the previous meeting had been read, Messrs. E. M. Prevost, Ph.D. and F. H. Hobler were formally admitted Fellows of the Society.

A list of the Donations made to the Society then followed, and the names of Messrs. Charles Lees, John Abigail Bower, Miles H. Smith, George Frederick Schacht, Alfred J. Cownley, and Walter E. Koch were read for the first time; for the third time, Messrs. Alfred Payne, George Combe Stewart, Robert Routledge, D.Sc., and George B. Beilby, who were then balloted for and duly elected.

The first paper entitled "*Analysis of Water of the River Mahanuddy*," by E. NICHOLSON, was read by the SECRETARY. The author first details the method he pursued in order to clarify waters which remain turbid even after standing for a long time, and also for determining the amount of suspended silt. This he effects by the addition of ammonium sulphate to the water, and subsequent concentration whereby the silt separates in flocks which are capable of being collected on the filter. He then proceeds to describe the position of the Mahanuddy river, its course, and the geological structure of its bed, &c.; and gives the results of his analyses of the water, from which he finds that it contains less dissolved matter than any other river in India; the total amount of mineral

solids being 0.12 grm. per litre, of which 0.0343 grm. was suspended silt. The hardness of the water by the soap-test was 5° of the centigrade scale.

Dr. WILLIAMSON said that, from the author's experiments, this water appeared to offer some points of difference from ordinary waters, especially the difficulty of separating the suspended matter. With regard to the process he adopts of treatment with ammoniac sulphate, it was a question how far it might alter the composition of the constituents of the water.

Mr. WARINGTON remarked that in the case of flood-water passing over a clayey soil, and which was very difficult to clear, it had been found that all salts, and especially calcium salts, caused a coagulation of the suspended matter, which greatly facilitated the subsidence of the silt and filtration of the water.

Mr. THORPE said that he could corroborate Mr. Warington's remarks. He had recently examined a turbid water which passed, apparently unaltered, through four thicknesses of Swedish filter-paper, but after treatment with sulphurous anhydride it became capable of being filtered. The difficulty in introducing such substances as precipitants was, that they are liable to take down other constituents of the water besides the suspended matter. He had found loam to be preferable to sand for filtering water.

In reply to a question of Dr. Warren de la Rue, Mr. THORPE further stated that he had frequently examined silts from flood-waters microscopically, but had never been able to detect any traces of organic life.

The CHAIRMAN observed that the use of sulphate of alumina to assist the clarification of waters in which the organic constituents were to be determined, as practised by the author, was highly improper; it was almost certain that a change would be produced. The same might be said of the effect of calcium chloride in waters containing acid silicates, some of the silica must be taken down. For his own part, he thought the most satisfactory plan was to allow the water time to settle.

The second paper "*Researches on the Polymerides of Morphine and their Derivatives*," by E. Ludwig Mayer and C. R. A. Wright, D.Sc., was read by Dr. WRIGHT, and illustrated with specimens of many of the substances mentioned. The memoir consisted of several papers, the first being on the action of zinc chloride on morphine. At low temperatures, and with concentrated solutions of the zinc salt, tetra- and dimorphine (apo-morphine) appears to be the principal product, but at higher temperatures and with the addition of strong hydrochloric acid a "tetra" polymeride of apo-morphine is formed, which may be called octa- or tetramorphine. The principal results enumerated in the second paper, "On the Action of Hydrochloric Acid on Morphine," are that besides apo-morphine mixtures of three bases are produced which may be written $M + 3\text{HCl}$, $M + 3\text{HCl} - \text{H}_2\text{O}$ and $M_4\text{HCl} - 2\text{H}_2\text{O}$, where M stands for morphine, $\text{C}_{17}\text{H}_{19}\text{N}_3\text{O}_5$. The action of sulphuric on morphine appears generally to yield polymerides without abstraction of water, the principal products being the sulphates of trimorphine, $\text{C}_{102}\text{H}_{114}\text{N}_6\text{O}_{18}$, and tetra-morphine, $\text{C}_{136}\text{H}_{152}\text{N}_8\text{O}_{24}$. The authors also describe the results of the action of hydrochloric acid on trimorphine and tetra-morphine and state the physiological action of the various bases, concluding with a table of the names, formulæ, &c., of no less than nineteen derivatives of morphia.

The CHAIRMAN in thanking the authors for laying before them the results of their elaborate researches, alluded to the wide field which they embraced, offering various interesting points for discussion.

Mr. PROSJEAN remarked that the subject was certainly a large one, and already sufficiently bewildering, so that he must protest against the use of some of the names which the authors had employed, more especially the introduction of prepositions into them. Some of the old names were certainly unwieldy enough, but he preferred them to such terms as apomorphine, in which there was nothing

to signify that it was derived from morphia by the abstraction of water. It might equally mean that anything else was taken away.

Dr. WRIGHT replied that the title was first employed by the late Dr. Matthiessen to signify that the substance was a derivative from morphia, and that it had now become a conventional term to signify the abstraction of water, and was certainly less a misnomer than such names as oxygen.

Mr. VERNON HARCOURT certainly thought that there was no reason for the introduction of prepositions into chemical names without any consideration of the fitness of the term. The prefix "apo" certainly gave no indication that the substance was a derivative formed by the abstraction of water.

Dr. H. E. ARMSTRONG then brought forward "Communications from the Laboratory of the London Institution, Nos. VIII.—X." In the first of these, entitled "*Derivatives of β -dinitrophenol*," he describes the mono-iodo-, chloro-, and bromo-derivatives of β -dinitrophenol, a compound produced, along with α -dinitrophenol, when the volatile modification of mononitrophenol is acted upon by nitric acid. The new compounds were prepared by the direct action of the corresponding halogen on the β -dinitrophenol. Iodo- β -dinitrophenol, obtained by the action of iodine and mercuric oxide on β -dinitrophenol, crystallises in bright yellow needles, which melt at 113° . The potassium derivative forms brilliant red flat needles, which exhibit a marked dichroism, the reflected light being metallic green in one direction, yellow in another. The corresponding bromo- β -dinitrophenol melts at 116° , and yields a yellowish brown potassium derivative.

In the second communication, "*Note on the Action of Bromine in presence of Iodine on Trinitrophenol (Picric Acid)*," the author first alludes to Dr. Stenhouse's experiments on the action of bromine on picric acid, and to his later experiments on the action of chlorine on picric acid in the presence of iodine, which yielded a chloro-dinitrophenol, and then states that he had also succeeded in isolating the first product of the action of bromine on picric acid, viz., bromo-dinitrophenol. The chloro-dinitrophenol obtained by Stenhouse is isomeric with the body formed by chlorinating α -dinitrophenol; hence it might have been expected that the corresponding bromo-derivatives would also be isomeric. The author finds that there is a very close resemblance between the bodies from the two sources, even if they be not actually identical; this, however, cannot be satisfactorily settled until the product from trinitrophenol has been obtained in a pure state.

A "*Preliminary Notice on Iodo-Nitrophenols*" then followed. The author has commenced the examination of these bodies in order to ascertain whether any definite relation exists between the melting-points of the iodo-, bromo-, and chloro-nitrophenols. In order to prepare these compounds, the nitrophenols, in alcoholic solution, were acted on by iodine and mercuric oxide. The iodo-dinitrophenol, from α -dinitrophenol, was found to melt at 105° , Körner giving 114° as its melting-point. The action of iodine on ortho-nitrophenol was found to give rise to the formation of diiodo-nitrophenol, melting at 155.5° , even when the quantity of iodine employed was only sufficient to form the monoiodo-derivative, nitrophenol remaining unacted on, a result similar to that obtained when acting on an alcoholic solution of phenol-parasulphonic acid by iodine and mercuric oxide, a diiodo-phenol-sulphonic acid being formed. In like manner, chlorine and bromine, when acting upon the same acid, give rise to the formation of di-substitution products. The author has also prepared the mono- and diiodo-derivatives of the volatile modification of nitrophenol.

The CHAIRMAN thanked the author, in the name of the Fellows, for his interesting communication and for the series of beautiful specimens with which he had illustrated it.

In reply to a question put by Dr. Wright, as to the

iodine substitution-compound having a lower melting-point than the chlorinated derivative, whilst the brominated one was higher, Dr. ARMSTRONG remarked that the relation of the fusing-points depended entirely on the series to which the substance belonged, and instanced several cases in which different relations subsisted between various haloid derivatives.

The last paper, a preliminary notice "*On the Formation of Naphthaquinone by the Direct Oxidation of Naphthalene*," by CHARLES E. GROVES, was read by the author, in which, after drawing attention to the fact that naphthaquinone itself had not yet been carefully examined, he described the method of preparing it by the action of chromic anhydride on naphthalene in solution in glacial acetic acid. The naphthaquinone is a crystalline body of a fine yellow colour, which, when boiled with strong hydriodic acid and phosphorus, takes up a molecule of hydrogen and becomes converted into hydro-naphthaquinone, a colourless substance crystallising in needles. When equal molecular weights of the quinone and the hydroquinone are boiled together in aqueous solution, an intermediate quinone, of a dark purple colour, is formed, corresponding to the green hydroquinone of the benzol series. The same substance is produced by the action of weak hydriodic acid on naphthaquinone.

Dr. ARMSTRONG remarked that it would be very interesting to try the action of chromic anhydride in a similar manner on the chlorinated derivatives of naphthalene, in order to ascertain whether they would yield quinones or split up with formation of phthalic acid.

The CHAIRMAN, after returning thanks to the author for his interesting communication, stated that the next meeting would take place on Thursday, January 16th, when papers would be read "*On Several Vanadates of Thallium*," by T. Carnelly; "*On Heptanes from Petroleum*," by C. Schorlemmer; and "*On Ethylamyl*," by Mr. Grimshaw.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 26th, 1872.

J.P. JOULE, D.C.L., LL.D., F.R.S., &c., President, in the Chair.

Dr. R. ANGUS SMITH, F.R.S., said that he, like others, had observed that the particles of stone most liable to be in long contact with rain from town atmospheres, in England at least, were most subject to decay. Believing the acid to be the cause, he supposed that the endurance of a siliceous stone might be somewhat measured by measuring its resistance to acids. He proposed, therefore, to use stronger solutions, and thus to approach to the action of long periods of time. He tried a few specimens in this way, and with most promising results. Pieces of about an inch cube were broken by the fall of a hammer, and the number of blows counted. Similar pieces were steeped in weak acid; both sulphuric and muriatic acids were tried, and the latter preferred. The number of blows now necessary was counted. Some sandstones gave way at once and crumbled into sand; some resisted long. Some very dense siliceous stone was little affected; it had stood on a bridge unaltered for centuries, in a country place, however. These trials were mere beginnings; he arranged for a very extensive set of experiments to be made, so as to fix on a standard of comparison, but has not found time.

"*On some Points in the Chemistry of Acid Manufacture*," by H. A. SMITH, F.C.S.

The author endeavours to throw some light on the interior economy of the lead chamber as at present used in the manufacture of sulphuric acid, by making first:—

An Experimental Examination of the Causes which Determine the Action, inter se, of the Gases in the Lead

Chamber.—The conclusion come to differed from that generally received. He believes that action can take place between dry sulphurous acid and nitric acid gases, without the use of steam, and showed by several experiments that, if action be commenced between the above-mentioned gases, it continues, even in the absence of air, till all the available oxygen present in the nitric acid has been made use of.

He also comes to the following conclusions:—

1. That the volume of steam introduced should be less than the combined volumes of the two gases.
2. That the volume of steam introduced should increase in proportion to the increase of temperature.

3. That the greatest amount of action between the two gases (and therefore the greatest yield of vitriol) takes place near the surface of previously-formed sulphuric acid, and that therefore in "starting" the working of a chamber sulphuric acid should be run upon the bottom in preference to water, as at present generally done.
4. That the upper part of the chamber is of use principally as a "reservoir," and that little or no action takes place between the gases at that part.

The next point claiming attention was:—

The Distribution of the Gases in the Lead Chamber.—
The following tables will show the results arrived at:—

SULPHUROUS ACID.—TABLE I.

Length of Chamber in feet.	10	20	30	40	50	60	70	80	90	100	110	120	130	140	Length of Chamber in feet.

GLASGOW PHILOSOPHICAL SOCIETY:
(CHEMICAL SECTION).

Ordinary Meeting, December 9th, 1872.

DR. WALLACE, F.R.S.E., President, in the Chair.

"The Volcanic Vapours of Mount Vesuvius." A paper by Mr. JAMES ANDERSON was read on this subject, giving an account of a visit to Vesuvius in the month of October, 1871. On approaching the mountain, thin white clouds were observed to issue from its side and top; they were persistent, and continued to float for a long time against the dark blue sky as far as the eye could follow them. It was, therefore, naturally inferred that these clouds were not steam or the vapour of water, otherwise they would have been dissolved in the dry, hot air which surrounded them in the same manner as the vapour issuing from the funnel of a locomotive.

Having accomplished about three-fourths of the ascent, the party arrived at the foot of the small cone which emitted one of the continuous clouds of vapour. From its crater the latest flow of lava was ejected, which took place a few months previously. Some of this lava was still fluid, flowing slowly under a solidified crust down the slopes of the mountain. On arriving at a precipice it trickled over and became visible, forming fiery streaks. This small cone which projected from the side of the mountain would not be more than 50, or at most 60, feet high. Its sides were rather steep, particularly towards the summit, and a considerable effort was necessary to reach the mouth of the crater; which would not be more than 8 or 10 feet in diameter, and the boiling lava which emitted the vapours was only 15 or 20 feet distant from the party. The thin wall of lava on which they leant for support, and which was the only thing to prevent them slipping into the crater, was not more than 6 inches thick at the edge; but it was firm, being formed of the fused lava and scoræ cemented together. The cloud of vapour generally filled the interior of the crater, and to the hand it felt hot and moist. Occasionally a gust of wind would blow the vapours to one side, and the red glare of the boiling-hot lava at the bottom could then be seen. Its vapours appeared white, somewhat dense, and, under the rays of the sun, had the granular or vesicular appearance of ordinary steam escaping into the atmosphere. The volume was not large, and just as it escaped from the summit of the cone it seemed to lose its vaporous appearance and to be resolved into a very thin white smoke, the surrounding dry hot air absorbing all the aqueous vapours. The walls of the crater were covered with a loose flocculent lining of a light gray colour, which adhered to the sides of the crater in the same manner as soot to the inside of a chimney, and had a depth of several inches. It seemed that this deposit was precipitated from the vapour as it ascended from the boiling lava below. Some of it was gathered close to the mouth of the crater, and an attempt was made to collect some as far down as the hand could reach, but it was too hot to be retained in the hand. Several hundredweights of this substance could have been gathered from the sides of the crater. A portion of this deposit was analysed by Mr. Michael Cochran, M.A., in the laboratory of the Glasgow University, and was found to contain per cent:—

Water	5.40
Silica	0.42
Oxide of copper	0.79
Peroxide of iron	15.43
Alumina	1.30
Oxide of manganese	0.07
Lime	0.28
Magnesia	0.32
Potash	22.04
Soda	14.10

Chlorine	4.58
Sulphuric anhydride	36.08

Less oxygen equivalent to 4.58 Cl. .	100.81
	1.03

99.78

The remarkable features of this analysis are the large proportions of potash, soda, iron, and sulphuric acid formed in the deposit, and the interesting inquiry suggests itself—"In what form did these substances exist in the molten lava? What gaseous compounds did they form when escaping from the red-hot lava? and how they would be affected on coming in contact with the atmosphere?"

Professor Phillips says that the composition of lava appears to be pretty uniform in all the periods of Vesuvian activity, and in one of the analyses quoted he gives the following as its composition:—

Silica	48.02
Lime	10.18
Alumina	20.78
Protoxide and peroxide of iron	7.97
Magnesia	1.16
Soda	3.65
Potassa	7.12
Sulphuric acid	trace
Chloride of sodium	trace
Water	trace

The guide accompanying the party imbedded a coin in the semi-fluid lava that was flowing down the side of the mountain. As the lava cooled, the coin became fixed in it. One of the party, Mr. H. J. Smith, a member of this Society, made a rough estimate of the potash, soda, and iron contained in the lava that adhered to the coin, and found the quantities of these substances to be fully as much as are given by Professor Phillips. The potash and soda exist in the state of silicates or aluminates, both of which are extremely fixed, even at very high temperatures. But in the presence of other gases a portion of the alkalis may be volatilised and separated from the silica and alumina. A very large quantity of steam is known to escape from the craters of active volcanoes. This steam would leave the lava at a very high temperature, and facilitate the escape of more or less of its volatile substances. It is well known that the presence of a gas in a liquid greatly facilitates the conversion of the liquid into vapour. Water does not of its own accord boil until it is raised to a temperature of 212° F.; but a cubic foot of air passed through it at a temperature several degrees below the boiling-point, will carry a cubic foot of steam along with it, and if alcohol, vinegar, hydrochloric acid, or other volatile liquids be mixed with the water, each would be carried off in proportion to its volatility. Glass is a species of lava containing a much larger proportion of potash or soda than natural lava. The glass maker has to protect his fused material from the hot gases of his furnace, to prevent them carrying off the potash and soda in the glass as vapour. When a piece of soft glass is kept fused for some time in the flame of a blowpipe, so much of the alkali is quickly carried away by the gases of the flame as to render the glass almost infusible. In the same manner, the steam and other gases passing through the red-hot molten lava may be expected to carry potash, soda, and other volatile substances along with them, these substances being again precipitated from the gases as they are cooled on the sides of the crater.

There is some difficulty in forming a satisfactory opinion as to where the water which forms the steam escaping from volcanoes comes from. But suppose the crust of the earth between the lava and the water of the sea to crack, and the water to rush in at the fissure, the moment it touched the hot lava it would be converted into steam, and unless the pressure be enormous the steam

formed would force the water back again. Should this action really take place, it seems sufficiently powerful to account in a great measure for the sea waves and earthquakes that accompany volcanic eruptions, and may even contribute largely to the eruption itself. A column of water having the diameter of the vent of Vesuvius and half the height of the mountain, would contain 30 to 40 million tons of water. Assuming this vast body of water to be urged from the vent into the sea with all the force that red-hot water, forming into steam, can impart to it, the rush would be powerful enough to generate a wave having inertia sufficient to carry itself so far inland as to submerge cities and leave the shipping of seaports high and dry on the land. Those who are in the habit of sailing in some of the Clyde steamers are familiar with the noise that accompanies the escape of steam into cold water when the vessel stops for passengers at the piers. Sometimes the thuds caused by the sudden condensation are so strong as to make the boat tremble. Only a very small quantity of steam is required to occasion each of these thumps as they are produced, at the rate of hundreds if not thousands per minute. If the end of the pipe that dips into the water were visible, it would be seen that the water rushes in and out with the rapidity of a weaver's shuttle, a shock being produced every time the water is drawn in and driven out. The cold water entering condenses the steam as it advances, until the water next it becomes so hot as to be unable to condense any more. The steam then forces the water out of the pipe, and as soon as the steam again comes in contact with the cold water, the same process is repeated. Now the steam that produced the wave would come in contact with the cold water of the sea. The moment it did so, it would begin to condense, forming a vacuum into which the sea-water would again rush, and, urged on by its own weight and the weight of the atmosphere, fly back towards the red-hot lava, and the lava towards it, with a force resembling the meeting of two railway trains multiplied a thousand or a million-fold. Should such an encounter take place, the sudden pressure resulting from the impact of such enormous masses at the point of junction would be sufficiently powerful to make the earth tremble.

It is difficult to conceive of conditions by which the water would force itself in amongst the fused lava, penetrating so far as to permit the steam formed to boil up through the lava at the top of the mountain. If some such conditions as exist in the Giffard injector were realised, then the water injected would become steam and produce all the effects required for an eruption. There is another way in which a quantity of water may find its way quietly into the lava. Some rocks and minerals, such as chlorite, schists, gypsum, zeolite, &c., contain a considerable quantity of water (not as water is contained in a sponge), but in chemical combination, as is the case in soda crystals. Supposing a current of lava to come in contact with such rocks, and that the temperature of the lava is sufficiently high to fuse these hydrated rocks, the water will either be relieved as a gas or steam, or retained in combination. Assuming the melting of the hydrated rocks to take place at a considerable depth, notwithstanding the very high temperature, there are several reasons for concluding that the water would fuse with the rocks, and form part of the liquid lava. First of all, the pressure may be enormous. Supposing the hydrated rock to be not lower than the base of the mountain, the pressure on it would be equal to 4000 feet of lava. A block of lava 1 foot long, having a cross section of 1 square inch area, would weigh about a pound, making the pressure on a square inch 4000 lbs., equal to 266 atmospheres. It is said that water can be made red-hot under a high pressure without being converted into steam; while it is well known that carbonic anhydride, hydrochloric acid, ammonia, and other gases can be reduced to the liquid form under high pressures, the condensation being greatly facilitated by the presence of a liquid. Under the ordinary pressure of the atmosphere, water converts many

gases into the liquid form, and the greater the pressure, the greater the quantity of gases absorbed and liquefied. There are certain facts that lead to the conclusion that very moderate pressures are sufficient to retain many gases in the liquid form, even at high temperatures, when other substances are present. Thus when oxide of silver is heated to redness it loses oxygen and becomes pure silver. But if the heat be continued until the silver melts, oxygen is re-absorbed from the air until twenty to thirty times the volume of the silver is absorbed. When the fused silver is allowed to cool, the oxygen boils out of it before it becomes solid. Here we have the same relation subsisting between fused silver and oxygen as subsists between carbonic acid and water. Before freezing, water parts with its carbonic acid gas in the same manner as silver parts with its oxygen. Seeing that silver absorbs and liquefies twenty to thirty times its own volume of oxygen under the pressure of the atmosphere, how much would it absorb and liquefy under the assumed pressure of 266 atmospheres? Ironfounders are very much annoyed by the tendency which iron has to absorb gases when fluid hot, and giving it out again while cooling; and they are put to some trouble to provide for its escape in such a manner as not to injure their castings. A head of metal is formed on the mould through which the gases escape, which supplies metal to the space occupied by the gases. The head is found to be in a frothy or spongy state, something like a piece of porous slag or lava. These small gaseous bubbles or cells are found to weaken the iron very much, and Whitworth's latest improvement in gunnery is the prevention of the formation of these cells by cooling the metal under a very great pressure. The gases are thus prevented from expanding, and are retained in chemical combination with the iron. In this manner, Sir Joseph Whitworth obtains a metal strong enough to enable him to make a gun capable of sending a shot or shell 7 to 8 miles. But it is not with fused metals only that gases have a tendency to combine at high temperatures. Slag from smelting furnaces absorbs and retains gases while hot, which are given out upon cooling. In the act of separating and expanding, the gases impart to the slag all the appearance of cellular lava. When carbonate of lime, such as chalk, or limestone is heated under pressure, the carbonic acid remains in combination with the lime and a fused carbonate of lime is obtained. If the pressure is removed before cooling, most of the carbonic acid assumes the gaseous form and escapes.

When oxide of lead, litharge, is heated until it fuses, it does not give out its oxygen as silver does, but absorbs more in the same way as melted silver; and what is more remarkable, when silver or litharge is heated with steam they combine with its oxygen and leave the hydrogen free. According to Deville, the oxygen is separated from the hydrogen by the heat before it combines with the silver or litharge.

The influence of heat under certain circumstances in separating chemically-combined substances into their elements is well known, while pressure has the opposite effect of causing chemical combination. In volcanic phenomena we have these two contending influences in great force, so great, indeed, that it is impossible by mere laboratory experiments to determine the result of their combined action. Judging from what we know, however, there seems to be room to conclude that at no very considerable depth the water, carbonic acid, and other gases escaping from volcanoes are in combination with the silica, alumina, lime, potash, soda, oxide of iron, and other substances which constitute the lava, and that they form one homogeneous fluid, in which all the ingredients are intimately mixed together. Such a lava moving obliquely or perpendicularly up the vent of a cone will experience a diminution of pressure as it ascends.

The more volatile substances will begin to assume the gaseous form, generating a mass of small cells which will expand a thousandfold as they ascend, converting the lava into a species of froth, from which the gases escape, on

arriving at the crater, like steam out of a boiling-over pot, or the gases out of a soda-water bottle when the cork is removed. The steam and gases so escaping form the white cloud seen to issue from every active volcano. When the watery vapour is absorbed by the surrounding air, there remains the thin persistent cloud formed of substances similar to that found in the deposit, but in a sublimed state.

If water form a constituent of the fused lava under pressure in the manner suggested, it is easy to account for the cells of water found in the crystals of which granite is composed. If lava were permitted to cool slowly under the required pressure, the elements of which it is composed would elect to crystallise into felspar, mica, and quartz, the water separating and forming cells in the crystals. Should the lava in the volcanic vent be in the cellular or spongy state supposed, it will be very susceptible to variations in the atmospheric pressure. As the pressure increases the cells will become smaller, and as it diminishes they will expand, the body of the lava expanding with them and filling the crater sometimes to overflowing. This seems to be confirmed by observations made on Stromboli, one of the Lipari group of islands in the Mediterranean, a volcano which has been in moderate activity from the time of Homer.

Dr. Wollaston says, "the inhabitants of Stromboli positively make use of the volcano as a weather-glass. They are mostly fishermen, and while engaged in their occupation at a short distance from the island have its orifice constantly in view; and I was assured by all whom I questioned on the subject that its phenomena decidedly participate in the atmospheric changes, increasing in turbulence as the weather thickens, and returning to a state of comparative tranquillity with the serenity of the sky."

In the boiling of the vapours out of the lava, and their condensation on the sides of the crater, there is a process of distillation going on whereby the more volatile metals and their compounds are separated from the more fixed silica, alumina, and lime. In the continuous operation of volcanic action it may be asked, "How far does this distilling or volatilising action contribute to the formation of metallic veins?" Here we have the means whereby metals such as gold, silver, copper, zinc, and iron may be separated from masses of fused lava which may not contain a thousandth part of these metals. Professor Phillips mentions only a trace of copper in the lava, while Mr. Cochran found about 0.8 per cent of cupric oxide in the deposit. To what extent these volatilised metals may fill up cracks and fissures, and contribute to the formation of veins of metals, is a question for the mineralogist and the geologist. The crater of Mount Vultur, in the centre of Italy, has been a lake from the time of Horace, and gaseous exhalations still proceed from it. If the gases and vapours from the lava pass up through the water, the copper, iron, potash, soda, and other substances contained in the vapours will be taken up by the water, and certain chemical actions may take place that would precipitate the oxides of iron, copper, and other metals to the bottom of the lake.

Mr. MICHAEL COCHRAN, M.A., made some remarks upon the analysis referred to in Mr. Anderson's paper. He described one specimen which he had received as a grey amorphous salt, having the appearance of a finely-divided ash. In composition it differed much from ordinary lava, no less than 84.3 per cent being soluble in water, and 99.58 per cent soluble in strong HCl. The small quantity of silica present, and the large quantity of sulphuric anhydride, indicated that it had been formed by a process of sublimation. When ignited over the Bunsen flame it lost 10 per cent of its weight, 5.4 per cent being moisture, the remainder being sulphuric anhydride, from certain of the sulphates present, and also chloride of sodium. He regarded the following as representing the form in which the substances given in the above analysis were combined:—

Sulphate of potassium	(K ₂ SO ₄)	..	40.80
" sodium	(Na ₂ SO ₄)	..	23.13
" copper	(CuSO ₄)	..	1.59
" aluminium	(Al ₂ SO ₄)	..	3.05
" manganese	(MnSO ₄)	..	0.14
" calcium	(CaSO ₄)	..	0.68
" magnesium	(MgSO ₄)	..	0.96
Sulphuric acid	(H ₂ SO ₄)	..	0.22
Chloride of sodium	(NaCl)	..	7.55
Ferric oxide	(Fe ₂ O ₃)	..	15.43
Silicate of alumina	..	..	0.78
Water	H ₂ O	..	5.40

99.73

Of the above substances, manganous sulphate was the only one which he had not seen noticed by other writers as occurring in similar situations. The substance was not perfectly stable, the small quantity of free sulphuric acid present producing a slight chemical change. The sublimate gathered from the exterior of the cone by Mr. Anderson differed from the other somewhat in external aspect; one portion was of a yellow colour, the other blue, both having an irregular crystalline structure. As the quantity was small, the yellow and the blue deposit were mixed together. The following shows the composition of the mixture:—

Oxide of copper	(CuO)	..	7.75
Oxide of alumina	(Al ₂ O ₃)	..	17.34
Oxide of iron	(Fe ₂ O ₃)	..	1.43
Lime	(CuO)	..	2.58
Magnesia	(MgO)	..	1.66
Potash	(K ₂ O)	..	4.02
Soda	(Na ₂ O)	..	3.94
Sulphuric anhydride	(SO ₃)	..	25.80
Chlorine	(Cl)	..	1.90
Fluorine	(F)	..	Small quantity
Silica	(SiO ₂)	..	16.90
Water	(H ₂ O)	..	17.10

100.42

Less oxygen equivalent to 1.9 Cl.. 0.42

100.00

The substances present were thus much the same as in the previous case, but in different proportions. The chlorine present was exactly in the proportion required to combine with the iron to form ferric chloride, thus accounting for the yellow colour of one specimen; the blue colour, on the other hand, was due to sulphate of copper. After pointing out the difficulty of supposing that the presence of the above-named substances in the volcano could be explained by the introduction of seawater, he went on to show how their presence might be accounted for. The alkalies would be derived from the lava itself, particularly from the more trachytic or felspathic sort, which is richer in alkalies and contains less of the ferruginous minerals. The alkaline silicates would be partly taken into solution by the interstitial water, which exists in all lavas while in the molten condition. Solution would be assisted by carbonic acid derived from the strata through which it ascended, and possibly also by a sulphuric acid. The subsequent reaction of sulphuric acid upon the dissolved silicate or carbonate would account for the fact of its being found in the form of sulphate. The sulphuric acid he thought would be derived from sulphides of the metals iron, &c. For, though iron pyrites was easily decomposed by heat at ordinary pressures, there was reason to believe it could exist at a high temperature if subjected to great pressure, it being a common constituent of the crystalline as well as of the sedimentary rocks. When the metallic sulphides arrived at a part of the volcanic vent suitable for oxidation, they would lose their sulphur, which would be burned to sulphurous anhydride, and in the hot moist atmosphere of the cone would be further oxidised to sulphuric acid.

Mr. Anderson's paper was illustrated by numerous

specimens of volcanic products, a number of which were collected in the year 1866 by Mr. Wünsch, a member of the Society, and by whom they were lent for the occasion.

An interesting discussion ensued, in the course of which Mr. Wünsch and Mr. Ogilvie gave some of their own observations made on Vesuvius, Etna, the Lipari Islands, &c. Mr. Tatlock, the President, and other gentlemen, also took part in the discussion. Some degree of surprise was expressed at the non-appearance of ammonium chloride in the results of Mr. Cochran's analysis, but that gentleman said he had purposely sought for it, and had failed to find any. In one of the deposits Mr. Anderson stated that Dr. Thorpe had found, by spectrum analysis, lithium in sensible quantity.

NOTICES OF BOOKS.

A Manual of Elementary Chemistry. By GEORGE FOWNES, F.R.S., late Professor of Practical Chemistry in University College, London. Eleventh Edition. Revised and corrected by HENRY WATTS, B.A., F.R.S. London: J. and A. Churchill. 1872.

Our students will welcome this new edition of Fownes's "Manual." It is printed in bolder type, and contains many additions to the subject of organic chemistry, as this division of chemical science is generally treated in handbooks. Mr. Watts's name is sufficient recommendation that the most recently-established facts have been included in the work. There is, however, one objection to the enlarged form—the volume becomes rather too bulky. This indeed is the most serious fault to be found with the book. The edition is a valuable one, and students should hasten to procure a copy.

Notes for My Students.—Magnetism. By WILLIAM J. WILSON, F.C.S. London: J. Bale and Sons. 1872.

THIS is a valuable addition to the many handbooks for students in Physical Science. It will be useful to the candidate for examination, or will afford notes to the lecturer.

MISCELLANEOUS.

Analyst and Medical Officer of Health for Birmingham.—At a special meeting of the Birmingham Town Council held on the 17th inst., the Mayor presiding, the Sanitary Committee recommended that candidates for the two offices mentioned above be advertised for at the salaries of £150 and £500 respectively; an amendment was, however, proposed by Mr. Rolason that Dr. Alfred Hill, the present borough analyst, be appointed to the two offices at the salaries named. This was seconded by Dr. Barratt. The motion was unanimously adopted by the Council, and Dr. Hill was accordingly appointed Medical Officer of Health for the borough.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus Hebdomadaires des Stances de l'Académie des Sciences, December 16, 1872.

This number contains, in addition to several memoirs relating to astronomy, meteorology, physics, natural history, and mechanical sciences, the following original papers relating to chemistry:—

On a Meteorite which fell near Baudong (Java) December 10, 1871, presented to Météor. d'Histoire Naturelle at Paris, by His Excellency the Governor-General of the Netherlands East Indies.—M. Daubrée. It appears from this exhaustive account that several rather large-sized meteoric stones fell on the same day at or near the locality above mentioned. According to the analysis of Dr. Vlaanderen, the stone consisted per cent of:—Nickeliferous iron, 28.1; sulphuret of iron, 5.44; chrome iron, 4.41; peridote, 47.26; augite, 20.98; feldspathic mineral, 17.0; total 97.90. 60.17 per cent of this stone is soluble in HCl. Its sp. gr. is = 3.519.

Detection of Bromine and Iodine in Native Phosphates of Lime.—F. Kuhlmann.—This paper opens with a review on the geognosy of the native phosphatic minerals, and on the occurrence occasionally observed of iodine and bromine in small quantity in some of these (as, for instance, the phosphorite of Staffel, near Limburg-on-the-Lahn). Next the author calls attention to the fact that when the phosphatic minerals of the Lot, and of the Tarn and Garonne Départements are treated with sulphuric acid on the large scale, vapours of iodine are distinctly seen; but on a minute investigation of the minerals the quantity of iodine, accompanied by some bromine (a very minute trace), is found to be exceedingly small.

On some of the Derivatives from the Oxychlorides of Silicon.—L. Troost and P. Hautefeuille.—This memoir treats on the action of the oxychloride of silicon, $\text{Si}_2\text{O}_5\text{Cl}_2$, upon alcohol. By a rather complex process of operation there is obtained an ether,— $(\text{C}_6\text{H}_5\text{O})_2\text{Si}_2\text{O}_{10}$

a mobile clear liquid; sp. gr. at $0^\circ = 1.071$; vapour density at 350° (boiling-point of mercury), 19.54. The ether is soluble in alcohol, and in ordinary ether, but not in water which gradually decomposes it, silica being precipitated. The authors next give an account of the action of ammonia on this ether, the result being the formation of an oily fluid, $(\text{C}_6\text{H}_5\text{O})_2\text{Si}_2\text{O}_{10}\text{NH}_3$; but by prolonged action of ammonia upon the ether alluded to, several other compounds are formed.

New Method of Producing Ozone by Means of Charcoal (Gas-retort Graphite).—A. Boillot.—The description of a series of experiments whereby, the graphite being used as a conductor of electricity, pure and dry oxygen is slowly and partially converted into ozone.

Estimation of the Quantity of Oxygen Dissolved in Rain and Seine Waters.—A. Girardin.—By Schützenberger's process (described in CHEMICAL NEWS, vol. xxvi, p. 204) the author has estimated the quantity of oxygen in rain-water which has fallen at various dates, from October 29 to December 8 last, and also in Seine water. The largest quantity of oxygen to the litre found in the former was found to amount to 8 c.c. per litre, in the latter, to 6 c.c. The smallest quantity of oxygen in rain-water amounted to 2.59 c.c. to the litre; and in Seine water, to 3.33.

Journal für Gasbeleuchtung und Wasserversorgung, No. 20, 1872.

The original papers contained in this number strictly relate to matters pertaining to gas- and water-works engineering and management.

No. 21, 1872.

In addition to subjects specially relating to gas- and water-works engineering and management, we meet here with—

Analysis of the Water now Supplied to the Town of Wiesbaden.—Dr. R. Fresenius.—Hardness of the water between four and five. Composition in 1000 parts:—Sulphate of potassa, 0.0024; chloride of potassium, 0.0003; chloride of sodium, 0.0067; nitrate of soda, 0.0013; nitrate of lime, 0.0006; carbonate of lime, 0.0116; carbonate of magnesia, 0.0107; silica, 0.0081; organic matter (expressed by the quantity of oxygen required for its complete oxidation), 0.0007.

Water Supply to the Buildings of the Great International Exhibition to be held in Vienna in 1873.—T. Wieck.—The total quantity of water to be supplied for all purposes, inclusive of fountains, driving of machinery, &c., amounts to 1240 cubic metres per hour,—a quantity sufficient for a population of 200,000.

Bulletin de la l'Académie Impériale des Sciences de St. Petersburg, Vol. xvii., No. 5, 1872.

This number contains, in addition to original memoirs relating to other sciences, the following original memoir containing chemical information:—

Microscopical Investigation of the Sanative Mud met with in the Salt-Water Lakes Sak and Mainak, Crimea.—N. Jelenow.—The mud of Sak was found to contain, by Goebel, in addition to some water, gases, and soluble salts, the following quantities per cent of other substances:—Organic matter, 2.7; sand found to contain—silica, 22.25 per cent; peroxide of iron, 7.24; alumina, 4.25; magnesia, 0.25 (this analysis was made in 1838). Haasbagen analysed the mud in 1849, and found, in addition to carbonate, phosphate, and sulphate of lime, the following constituents per cent:—Silica, 37.80; peroxide of iron, 9.52; alumina, 8.30; magnesia, 5.82; organic matter, 3.75. The mud of Lake Mainak and the water of that lake have been analysed by Major-General Iwanow, and found to contain respectively in 100 parts—the mud: carbonate of lime, 28.99; carbonate of magnesia, 3.69; chloride of sodium, 8.565; chloride of magnesium, 0.793; sulphate of lime, 3.79; sulphate of magnesia, 0.457; bromide of magnesium, a trace; and sand and clay inclusive, 3 per cent; organic matter,

20° 81; water, 30° 00. It appears that these muds are used medicinally as baths in some forms of gout and chronic rheumatism.

La Revue Scientifique de la France et de l'Etranger,
December 14, 1872.

This number contains no papers relating to chemistry, but we call attention to the following memoirs:—

What we Gain by the Use of Manure in Agriculture.—G. Ville.—The continuation of the author's lectures on practical agriculture at Vincennes.

The Part Played by Glaciers in Geology.—A. De la Rive.
The Spectrum Exhibited by the Metalloids.—G. Salet.—An abstract of the author's inaugural dissertation read before the Faculty of Sciences at Paris.

Bayerisches Industrie und Gewerbe-Blatt, November, 1872.

This number contains no original papers relating to chemistry.

Bulletin de l'Académie Royale des Sciences, des Lettres et de Beaux Arts de Belgique, Nos. 9 and 10, Double Number, 1872.

This number contains no papers relating to chemistry.

American Journal of Pharmacy, December, 1872.

The original papers and essays contained in this number only relate to pharmaceutical sciences.

Revue Hebdomadaire de Chimie Scientifique et Industrielle,
November 21, 1872.

The Soap-boiling Industry at Dijon.—Sirandré and Co.—The detailed account of the methods of preparation of soap as carried on at the works of the parties referred to.

Similitude, a Liquid to be Applied Instead of Linseed Oil. M. Petit.—It appears that the author has succeeded in preparing a liquid—the nature, composition, and mode of preparation of which is not specified—which while it possesses all the valuable qualities of linseed oil, does not, when mixed with pigments and applied to iron, wood, or other objects, become deteriorated by exposure to weather, and is not affected by heat as linseed oil is.

Moulin-Mercier.—Under this heading an account is given of an improved mill-work for grinding corn. The main advantages of this contrivance are,—that less motive power is required; that the mill-stones have to be less frequently burred; that the flour does not become heated, and that consequently a larger yield of flour as well as a better quality is obtained.

November 29, 1872.

Ceresine, a New Hydrocarbon which may be Employed as a Substitute for Bees'-Wax.—Ch. Méné.—It appears that ceresine is a by-product of the industrial process employed for purifying the native ozokerite met with in Austria, which is used for the purpose of obtaining paraffine. The crude ceresine is treated with sulphuric and sulphurous acids, and, lastly, with alkalis: the pure article is a white-coloured, semi-transparent, opaline body, void of taste and smell, fusing at from 61° to 63°, sp. gr. 0.880, insoluble in water, soluble in alcohol, not saponified by alkalis. Ceresine is used in Vienna instead of wax in some pharmaceutical preparations.

Description of a New Instrument for Taking Levels.—M. Bigot.—Illustrated by woodcuts.

Bibliography.—Under this heading the following work is quoted:—*La France Industrielle, ou Description des Industries Françaises,* par M. P. Poiré, Professeur à l'Ecole Industrielle d'Amiens; 1 vol., 755 pp., 432 engravings; price 10 francs; Librairie Hachette, Paris. This work is highly spoken of, and is useful both for schools and for general reference.

Les Mondes, December 12, 1872.

Le Fondateur des Mondes et des Salles du Progrès.—Victor Fournel.—The article here reproduced from *Le Français* is called attention to as containing some biographical particulars of the excellent and reverend editor of *Les Mondes*, who, according to the testimony of Dumas, as lately publicly stated by him in a meeting of the Academy of Sciences, "marche depuis près d'un demi-siècle à la tête du mouvement scientifique en France;" and who, next to the late A. Dumas, has written and edited more books than any one else in France.

Tachymètre.—P. Dupont.—Under this heading a short account is given of an instrument which appears to be devised for the purpose of rendering the teaching of geometry a rapid and pleasant course at schools; M. Lagout has given some lectures to prove this at Clermont-Ferrand, the result being that the *Maire* and the *Recteur* have decided that tachymetry shall be introduced into the schools under their control. The instrument is made in three different sizes, at the price respectively of 10, 21, and 100 francs; it is for sale at 41, Rue J. J. Rousseau, Paris.

Cause of the Blue Colour of the Sky.—M. Collas.—The author first refers to the blue colour exhibited by the pure water of certain lakes, and says that it is due to the therein dissolved or very minutely divided gelatinous silica, quoting as instances the lake of Genève, the water of the d'Huis, and more particularly the water of a source near to the Mont-Dore (Département du Puy-de-Dôme), which water is even bluish-coloured when placed in a white glass decanter. The blue colour of the sky is referred by the author to the same cause, viz., very finely divided gelatinous silica (hydrated silica) kept in suspension in the clouds on account of its great lightness.

PATENTS.

Communicated by Messrs. VAUGHAN and SON, Patent Agents,
54, Chancery Lane, London, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

3160. W. T. Cooper, Oxford Street, Middlesex, "Improvements in preparing or making up medicated and other effervescing mixtures."—Petition recorded October 24, 1872.

3232. W. T. Cooper, Oxford Street, Middlesex, "An improvement in the manufacture of lozenges."—Petition recorded October 31, 1872.

3464. E. Hills, Warsash, Hampshire, and E. Biggs, Laurence Pountney Hill, London, "Improvements in deodorising and purifying sewage and other excrementitious matters, and in obtaining certain useful products therefrom."—Petition recorded November 20, 1872.

3477. P. Jensen, Chancery Lane, Middlesex, "Improvements in the manufacture of steel."—A communication from T. Brooks, Minerva, Stark, U.S.A.—Petition recorded November 21, 1872.

3628. C. Von Hennings, "The preparation of an extract from the berries of the mountain ash (Pyrus), (German, Eberesche)."—Petition recorded December 2, 1872.

3642. C. W. Siemens, Great George Street, Westminster, "Improvements in smelting iron and steel, and in furnaces and apparatus employed in connection therewith, parts of which improvements are also applicable to regenerative gas furnaces generally."

3643. F. J. Bolton, Grosvenor Mansions, Westminster, "Improvements in compounds for coating leather in order to render it more enduring and less pervious to moisture."—Petitions recorded December 3, 1872.

3668. W. E. Newton, Chancery Lane, Middlesex, "Improvements in the manufacture of cast-steel, and in refining pig- or cast-iron."—A communication from B. Gloeckner, Tschirndorf, Prussian Silesia.

3670. H. Y. D. Scott, C.B., and T. W. Scott, Ealing, Middlesex, "Improvements in the mode of, and apparatus for, preparing lime for the treatment of sewage."—Petitions recorded December 4, 1872.

3676. F. G. Morton, Bermondsey, Surrey, "An improvement in treating tin-plate waste scraps or clippings for separating or removing the tin and other matters from the iron."

3678. W. R. Lake, Southampton Buildings, London, "Improvements in the manufacture of malleable cast-iron and cast-steel, and in furnaces therefor."—A communication from J. M. Roberts, Burlington, New Jersey, U.S.A.

3680. T. Petitjean, Islington, Middlesex, "Improvements in the production of metallic surfaces and articles of various forms by chemical means and the electro-deposition of metals, which surfaces or articles are produced either highly polished, dead or matted, engraved, or otherwise ornamented."—Petitions recorded December 5, 1872.

INVENTION PROTECTED FOR SIX MONTHS BY THE DEPOSIT OF A COMPLETE SPECIFICATION.

3737. W. R. Lake, Southampton Buildings, London, "An improved method of clarifying and settling varnishes, oils, and other like substances."—A communication from F. Kersting, Grand Rapids, Michigan, U.S.A.—Petition recorded December 9, 1872.

NOTICES TO PROCEED.

2328. E. Packard, jun., Ipswich, Suffolk, "Improvements in the manufacture of superphosphate of lime and artificial manure."—Petition recorded August 3, 1872.

2342. W. R. Lake, Southampton Buildings, London, "An improved ink-erasing compound."—A communication from J. C. de Voy, San Francisco, California, U.S.A.—Petition recorded August 6, 1872.

2369. W. R. Lake, Southampton Buildings, London, "Improved nutritious compounds."—A communication from J. R. Weed, New York, U.S.A.—Petition recorded August 9, 1872.

2403. A. M. Clark, Chancery Lane, Middlesex, "A new or improved medicinal compound."—A communication from C. V. Viard, Paris, France.—Petition recorded August 12, 1872.

2649. W. Meister, Dr. E. Lucius, and Dr. A. Brüning, Hoechst, near Frankfurt-on-the-Maine, Germany, "Improvements in the manufacture of colouring-matter suitable for dyeing and printing."—Petition recorded September 6, 1872.

2672. E. Withy and W. Gibson, West Hartlepool, Durham, "Improvements in puddling furnaces, and in preparing iron for being operated upon therein and charging, such improvements in preparing for and charging being applicable in connection with cupolas, vibratory, and refinery furnaces."—Petition recorded September 9, 1872.

3330. A. C. Pelly, Finch Lane, London, "Improvements in the manufacture of peat-fuel, and in the machinery and apparatus therefor."—A communication from L. Von Hom, Stockholm.—Petition recorded November 9, 1872.

PATENTS SEALED.

1769. J. Dupont, Nîmes, France, "The application and treatment of certain plants not hitherto used for the production of filaments and fibres."
1770. J. Birch, Newton Heath, Lancashire, "Improvements in the manufacture of iron and steel, and in apparatus to be used in such manufacture."—Dated June 12, 1872.
2930. J. G. N. Alleyne, Alfreton, Derbyshire, "Improvements in apparatus for the manufacture and refining of sugar and rum or other spirit."—Dated October 4, 1872.
3005. C. Lowe, Reddish, Lancashire, "Improvements in the treatment of coal-gas tars, for the purpose of obtaining certain useful products therefrom."—Dated October 11, 1872.

NOTES AND QUERIES.

Analysis of Hyposulphites, Sulphides, and Sulphites.—Can any of your readers give me a method to estimate sulphide, hyposulphite, and sulphite of sodium in the same solution?—**ALKALI.**

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.
Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.
Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.
Aluminium and Sodium: Stannates, Tungstates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.
Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

BAILLIERE AND CO., 20, King William Street, Strand.

Now ready, demy 8vo., with 8 Lithographic Plates and a Chromo-Lithograph, 7s. 6d.,

An Index of Spectra. By W. Marshall Watts, D.Sc. With a Preface by Professor Roscoe, F.R.S.

"The author deserves the hearty thanks of scientific spectroscopists for the arduous task he has so well discharged. . . . Excellent plates accompany the volume. . . . A careful and well done piece of work."—*Popular Science Review*.

"All has been done that will in any way assist the spectroscopist. . . . The work will be found equally as useful with instruments of only one or two prisms as with the largest spectroscopes."—*The Chemical News*.

"The attention the author has bestowed on this work is the best guarantee of the accuracy of the numbers given. . . . It is to be hoped that his "Index of Spectra," may contribute to the adoption of a uniform scale of measurement, and thus facilitate the advance of the science."—*Nature*.

"His work needs no recommendation; it will be, if it has not already been, placed on the shelves of every scientific library."—*Quarterly Journal of Science*.

London: Henry Gillman, Boy Court, Ludgate Hill, E.C.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

BERNERS COLLEGE of CHEMISTRY.—EXPERIMENTAL MILITARY and NAVAL SCIENCES, under the direction of Professor E. V. GARDNER, F.E.S., &c., of the late Royal Polytechnic Institution and the Royal Naval College.

The Laboratory and Class Rooms are open from 11 to 5 a.m., and from 7 to 10 p.m. daily.
Special facilities for persons preparing for Government and other examinations.

Private Pupils will find every convenience.
Analyses, Assays, and Practical Investigations connected with Patents, &c., conducted.

For prospectus, &c., apply to Prof. E. V. G., 44, Berners-street, W.

Royal Polytechnic Institution, 309, Regent Street.—Laboratory (entirely re-fitted) and Class-Rooms are now open.

ASSAYS, ANALYSES and Investigations connected with PATENTS conducted.

Pupils received for Class and Private Study. Special facilities are offered to persons preparing for GOVERNMENT EXAMINATIONS.

Classes are now forming for Practical Study in CHEMISTRY, STEAM, and PHYSICS.

For particulars, apply to Professor E. V. GARDNER, F.A.S., M.S.A., at the Institution.

North London School of Chemistry, Pharmacy, &c.—Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

The Session 1872-1873 will commence on the 1st of October, when—

The LABORATORY will be open at 10 a.m. for instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Terms moderate.

The CLASSES will meet as usual.

The CHEMICAL and TOXICOLOGICAL CLASS on Monday and Thursday evenings at 8 p.m., commencing October 1st.

The LATIN CLASS on Tuesdays and Fridays at 8 p.m., commencing October 2nd.

The MATERIA MEDICA and BOTANICAL CLASS, every Wednesday and Saturday at 8 p.m., commencing October 3rd.

The BOTANICAL GARDEN affords to Students desirous of acquiring a Practical Knowledge of Botany every facility for doing so. During the Season BOTANICAL EXCURSIONS are made every Saturday at 10 a.m.

Fee to either of the above Classes Half-a-Guinea per Month. Pupils can enter at any period to either Classes or Laboratory.

All Fees must be paid in advance.

PRIVATE TUITION for the usual Examinations of the Society, the Modified Examination, &c.

Letters of inquiry should be accompanied with a stamped envelope.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2½d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ship's Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT of MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian and other Governments.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soapery, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C., who hold stock ready for delivery.

 Wine, action of sulphuric acid on, 83
 beer, and vinegar testing, 23
 estimation of acetic acid in, 157
 Wines, chemical investigation of, 241
 improvement by heating, 82
 Winkler, C., aluminium plating, 157
 future of the gold-plating industry, 301
 relation of modern chemistry to metallurgy, 107
 Wislicenus, J., observations on the so-called anhydrides of lactic acid, 228
 Whiskey, destruction of the empyreumatic flavour of, 118
 White gunpowder, 288
 White-lead, red colour in, 35, 178
 Woestyn, M., beet-root sugar extraction, 48
 Wohler, F., analysis of the meteoric iron of Oviak, in Greenland, 12
 Wolff and Sons, application of the water air-pump to evaporation, distillation, filtration, &c., in vacuum, 156
 Wood vinegar manufacture, 229
 Woolf's tubes, improved safety tubes instead, 83
 Woodward, C. J., modification of Koffmann's apparatus for electrolysis of water, 97
 Woollen goods, mordanting with alum, 48
 Wood, W. H., Cavendish Society, 21
 Wreden, F., camphoric acid, 71
 reduction of isoxylol and of the aromatic hydrocarbons in general, 59
 Wright, A. W., simple apparatus for the production of ozone with electricity of high tension, 113
 C. R. A., possible reactions that yielded negative results, 238
 specific heat of occluded hydrogen, 287
 and E. L. Mayer, researches on the polymerides of morphine and their derivatives, 306
 Wurtz, M., abnormal density of perchloride of phosphorus, 205
 estimation of lithia in mineral waters, 181
 YEAST germ, experiments to prove whence derived, 192
 Young, J. F. action of heat and pressure upon paraffin, 35
 Young, J. W., arsenic in colours, 105
 Yttrium and erbium compounds, 228, 264
 Ytrotantalite, composition of the black, 265
 ZETTERLAND, M., preparation of alcohol from saw-dust, 181
 Zenaffsky, O., quantitative estimation of the alkaloids contained in Ipecacuanha, aconite, nicotiana, and conium, 95
 Ziegler, H. F., peculiar cases of gas leakage and poisoning by gas, 119
 E., oxidation of camphor cymol in the animal body, 229
 Zinc for tinning, 47
 methyl, action of bromated bromide of acetyl on, 265
 red oxide of, 169
 Zincke, T., hexyl-alcohol from heracleum oil, and on the capronic acid prepared from it, 11
 nonylic acid (probable), normal, 229, 277
 some of the derivatives of benzyl-toluol, 94
 Zulkowsky, K., influence of caoutchouc tubing on illuminating power of coal-gas, 229

Wood 100.
